Part 2 (primarily 2019 and on): Many references about buckling, wrinkling, crushing, crippling, crumpling, creasing, kinking, dimpling, folding, snapping, vibration, dynamic response and optimization of membranes, films, sheets, plates, panels, shells, tubes, nanotubes, pipes, thin-walled beam-columns, sandwich structures and soft structures.

Part 2 was introduced after Part 1 reached a length of almost 10000 pages. (NOTE: After a computer system update in June 2019 the length of Part 1 became about 8600 pages because more material now fits on a single page. Also, Part 2 became about 2200 pages, reduced from about 2600 pages for the same reason. At the end of 2020 Part 2 had about 7000 pages.) From now on Part 1 will remain essentially unchanged (except for the correction of errors, the inclusion of lists of references at the ends of a few articles for which these lists were previously unavailable, and the inclusion of previously unrecognized book titles in one of the Part 1 sections entitled “Book Cover Gallery”). All additional citations will be included in Part 2. This includes citations dated 2019 or after; citations of previously published papers not included in Part 1; citations of some earlier papers on fluid-structure interaction; citations of some earlier papers on chaos and nonlinear dynamic response; citations of papers (published from 2014 on) from the additional journals: Nonlinear Dynamics, Smart Materials & Structures, Soft Matter, Earthquake Engineering & Structural Dynamics, Shock and Vibration, Mathematical Problems in Engineering, Journal of the International Association for Shell and Spatial Structures, The Journal of the Acoustical Society of America, Structural and Multidisciplinary Optimization, Journal of Applied and Computational Mechanics and possibly from other journals not included in the list given at the beginning of Part 1. In March 2019 the citations of papers from 2014 - 2018 in International Journal of Structural Stability and Dynamics and the citations of papers from 2016 - 2018 in International Journal of Applied Mechanics were transferred from Part 1 to Part 2 in order to be able to include the list of references associated with each relevant citation without exceeding 10000 pages in Part 1.

With few exceptions, from now on all future effort on documenting the “shell buckling/vibration” field will generate additional entries only in Part 2 and in the image galleries of this website: “book cover gallery”, “shell buckling people” and “shell buckling images”

ABSTRACT: It is necessary to provide the separation of the eigenmodes of elastic objects from the sensor signals and to make it possible to independently affect the modes with the use of actuators when realizing the
modal system of controlling an elastic object with distributed parameters. The present paper puts forward an identification procedure which allows separating the vibration modes of the object in measured and control signals in the absence of the object model simulation. The control operability of this procedure was verified by experiment through making a system of active suppression of forced bending vibrations of a metal beam. The experiment showed the high control efficiency of the realized modal system.

ABSTRACT: In the present paper, a review on piezoelectric sensing of mechanical deformations and vibrations of so-called smart or intelligent structures is given. After a short introduction into piezoelectric sensing and actuation of such controlled structures, we pay special emphasis on the description of some own work, which has been performed at the Institute of Technical Mechanics of the Johannes Kepler University of Linz (JKU) in the last years. Among other aspects, this work has been motivated by the fact that collocated control of smart structures requires a sensor output that is work-conjugated to the input by the actuator. This fact in turn brings into the play the more general question of how to measure mechanically meaningful structural quantities, such as displacements, slopes, or other quantities, which form the work-conjugated quantities of the actuation, by means piezoelectric sensors. At least in the range of small strains, there is confidence that distributed piezoelectric sensors or sensor patches in smart structures do measure weighted integrals over their domain. Therefore, there is a need of distributing or shaping the sensor activity in order to be able to re-interpret the sensor signals in the desired mechanical sense. We sketch a general strategy that is based on a special application of work principles, more generally on displacement virials. We also review our work in the past on bringing this concept to application in smart structures, such as beams, rods and plates.

ABSTRACT: Thick-walled tubes made from isotropic and anisotropic materials are subjected to an internal pressure while the semi-analytical method is employed to investigate their elastic deformations. The contribution and novelty of this method is that it works universally for different loads, different boundary conditions, and different geometry of analyzed structures. Moreover, even when composite material is considered, the method requires no simplistic assumptions. The method uses a curvilinear tensor calculus and it works with the analytical expression of the total potential energy while the unknown displacement functions are approximated by using appropriate series expansion. Fourier and Taylor series expansion are involved into analysis in which they are tested and compared. The main potential of the proposed method is in analyses of wound composite structures when a simple description of the geometry is made in a curvilinear coordinate system while material properties are described in their inherent Cartesian coordinate system. Validations of the introduced semi-analytical method are performed by comparing results with those obtained from three-dimensional finite element analysis (FEA). Calculations with Fourier series expansion show noticeable disagreement with results from the finite element model because Fourier series expansion is not able to capture the course of radial deformation. Therefore, it can be used only for rough estimations of a shape after deformation. On the other hand, the semi-analytical method with Fourier Taylor series expansion works very efficiently.
well for both types of material. Its predictions of deformations are reliable and widely exploitable.

ABSTRACT: This paper deals with free flexural vibration modes and natural frequencies of a thin plate with general boundary conditions — a simply supported plate connected to its surroundings with torsional springs. Vibration modes were derived on the basis of the Rajalingham, Bhat and Xistiris approach. This approach was originally used for a clamped thin plate, so its adaptation was needed. The plate vibration function was usually expressed as a single partial differential equation. This partial differential equation was transformed into two ordinary differential equations that can be solved in the simpler way. Theoretical background of the computations is briefly described. Vibration modes of the supported plate with torsional springs are presented graphically and numerically for three different values of stiffness of torsional springs.

ABSTRACT: In this paper, single variable beam theories taking into account effect of transverse shear deformation are developed and applied for the bending, buckling and free vibration analysis of thick isotropic beams. The most important feature of the present beam theories is that unlike any other higher order theory, the proposed class of theories contains only one unknown variable and does not require shear correction factor. The displacement field of the present theories is built upon the classical beam theory. The theories account for parabolic distribution of transverse shear stress using constitutive relations, satisfying the traction free conditions at top and bottom surfaces of the beam. Governing differential equation and boundary conditions of these theories are obtained using the principle of virtual work. Results obtained for the displacements, stresses, fundamental frequencies and critical buckling loads of simply supported isotropic solid beams are compared with those obtained by other theories to validate the accuracy of the present theories.

ABSTRACT: A prior knowledge of group velocities of Lamb wave modes is a key for analysis of time signals in guided-wave based structural health monitoring. The identification of multiple wave modes may be complicated due to dependency of group velocity on frequency (dispersion). These dependencies for infinite plate of constant thickness can be calculated by a numerical solution of analytic equation. Two alternative approaches to determine group velocities of zero-order Lamb wave modes in aluminum plate were used in this work: Two-dimensional Fast Fourier Transform (2D-FFT) and methods of time-frequency processing. 2D-FFT requires a high number of time signals in equidistant points, therefore it was applied on data from finite element analysis of wave propagation in the plate. Group velocities for chosen frequencies were also determined using wavelet transform (WT) of signals as differences of times of arrival measured by a pair of piezoelectric transducers. The results from 2D-FFT and wavelet transform were compared to the analytic solution.

ABSTRACT: Thin-walled cylindrical shells are used as main structural components in various branches of engineering. Buckling is the key design criterion for these thin-walled structures. Cylindrical shells typically exhibit unstable post-buckling behavior and their behavior is correspondingly very sensitive to small geometric or load imperfections. In this paper, an approach to assess the modal interaction characteristics of composite cylinders under axial loading and their effects on the load carrying capability is presented.

In recent years, extensive research, including the NASA Shell Buckling Knock-Down Factor (SBKDF) project, has been carried out in order to develop design approaches that lead to appropriate, not too conservative design loads [1-4]. Both deterministic and probabilistic approaches are under investigation within the EU FP7 project DESICOS. An important deterministic approach further pursued within DESICOS is the Single Perturbation Load Approach.

An alternative deterministic approach to define knock down factors is based on Koiter’s imperfection sensitivity theory. This theory has been applied to the buckling of composite shells both within a semi-analytical context [5] and within a Finite Element framework [6]. In [5], Koiter’s initial postbuckling theory was employed using a numerical solution of the governing Donnell-type differential equations, while in [6] a Finite Element based reduced order model with a small number of representative modes was used. In [6] it was shown that for a given imperfection pattern, for small imperfection amplitudes the limit-point buckling loads obtained with the reduced order model compare reasonably well with full model nonlinear analysis. The objective of the present work is to investigate the characteristics of specific relevant modal interactions and to determine how these interactions affect the decrease of the load carrying capability of composite shells.

In the present work, studies using both the semi-analytical and the Finite Element implementation of Koiter’s theory are carried out in order to identify relevant modal interactions for composite shells under axial loading. Using representative imperfection patterns, both modes affine to buckling modes and appropriate specific modes, for certain composite shells the reduction of the load carrying capacity is established.

ABSTRACT: A probability-based analysis method for predicting buckling loads of compression-loaded laminated-composite shells is presented, and its potential as a basis for a new shell-stability design criterion is demonstrated and discussed. In particular, a database containing information about specimen geometry, material properties, and measured initial geometric imperfections for a selected group of laminated-composite cylindrical shells is used to calculate new buckling-load knockdown factors. These knockdown factors are shown to be substantially improved, and hence much less conservative than the corresponding deterministic knockdown factors that are presently used by industry. The probability integral associated with the analysis is evaluated by using two methods; that is, by using the exact Monte Carlo method and by using an approximate
First-Order Second-Moment method. A comparison of the results from these two methods indicates that the First-Order Second-Moment method yields results that are conservative for the shells considered. Furthermore, the results show that the improved, reliability-based “knockdown” factor presented always yields a safe estimate of the buckling load for the shells examined.

ABSTRACT: The post-buckling behaviour of panels can be very sensitive to imperfections or variations in materials or geometry. This paper presents an efficient numerical model to calculate the effects of material stiffness variations on the non-linear response of a structure. This is done by first defining a geodesic mesh on which a unit variance random field is generated. This field uses the true geodesic distance on the structure to calculate how points in the field should be correlated. The fields generated are projected onto a 3D structural mesh which is used for assembly and post-processing of the structural model. The structural model, based on the Unified Formulation is capable of accurate non-linear calculations of both straight and curved elements. Baseline results generated using the implementation are compared to those in literature, and verified using Abaqus. Random material variations are then applied to the structure in a Monte Carlo analysis. The analyses show that the local variation of stiffness can have a variety of effects on the non-linear response of structures. Aside from the change of mean stiffness causing a change in bifurcation or limit point load, the different stiffness distributions can affect and trigger competing buckling modes and post-buckling modes and affect their corresponding post-buckling load-deflection paths.

ABSTRACT: In order to identify abilities and deficiencies of available analysis tools as well as to establish recommendations for buckling, post-buckling and collapse analysis of thin-walled aerospace structures the Group for Aeronautical Research and Technology in EURope (GARTEUR) launched a specific Action Group consisting of 10 partners from universities, research establishments and industry out of 7 European nations. These partners identified three different benchmarks with well-documented buckling tests. Then, finite elements tools to simulate the structural behaviour were methodically checked and selected, the benchmark computations were performed, evaluated and recommendations were derived. This paper reports on the results of Benchmark 3, an axially compressed CFRP panel that consists of a skin with nominally cylindrical shape, stiffened by stringers. The stringers were partially separated from the skin by impacting prior to the tests. Finally, the panel was axially compressed until collapse. DLR, the University of Karlsruhe, QinetiQ and Samtech applied different tools to simulate the behaviour of this panel during loading up to collapse. Linear and nonlinear analyses as well as buckling analyses were performed. Specific abilities and deficiencies of the tools considered were evaluated. Finally, based on the experience gained within the project, the partners derived recommendations with respect to the influence of parameters, the initial buckling load, the convergence behaviour, the simulation of load introduction and boundary conditions as well as the imperfection sensitivity.

ABSTRACT: This paper presents two new design tools for lightweight aerospace structures. The first tool is the Tailored Fibre Placement (TFP) design tool TACO. It is used to optimize the fibre orientations of structures made of Carbon Fibre Reinforcement Plastics (CFRP). The optimization concept is explained and results are given for a horizontal tail plane connection beam of an aircraft. The second tool, iBuck, is a fast, semi-analytical local buckling and post-buckling tool for stiffened panels that are loaded in-plane. The panels are assumed to be representative for an aircraft fuselage and are stiffened in axial and circumferential direction. Results are
presented for axially loaded panels and compared to FE-results.

ABSTRACT: Cylindrical shells under axial compression are susceptible to buckling and hence require the development of enhanced underlying mathematical models in order to accurately predict the buckling load. Imperfections of the geometry of the cylinders may cause a drastic decrease of the buckling load and give rise to the need of advanced techniques in order to consider these imperfections in a buckling analysis. A deterministic buckling analysis is based on the use of so-called knock-down factors, which specifies the reduction of the buckling load of the perfect shell in order to account for the inherent uncertainties in the geometry. In this manuscript it will be shown that these knock-down factors are overly conservative and that the fields of probability and statistics provide a mathematical vehicle for realistically modelling the imperfections. Furthermore, the influence of different types of imperfection on the buckling load will be examined and validated with experimental results.

ABSTRACT: A methodology for analysing the degradation and collapse in postbuckling composite structures is proposed. One aspect of the methodology predicts the initiation of interlaminar damage using a strength criterion applied with a global-local analysis technique. A separate approach represents the growth of a pre-existing interlaminar damage region with user-defined multi-point constraints that are controlled based on the Virtual Crack Closure Technique. Another aspect of the approach is a degradation model for in-plane ply damage mechanisms of fibre fracture, matrix cracking and fibre-matrix shear. The complete analysis methodology was compared to experimental results for two fuselage-representative composite panels tested to collapse. For both panels, the behaviour and structural collapse were accurately captured, and the analysis
methodology provided detailed information on the development and interaction of the various damage mechanisms.

ABSTRACT: With the evolution of composite materials and moreover of the manufacturing process of large composite structures, a new window of possibilities is opened from the optimization point of view. Currently, one has great materials and reliable manufacturing processes than can be used for extremely optimized structures. The problem is that even nowadays, some calculation processes make use of design guidelines based on data from 50 years ago, which limits the optimization process due to outdated allowable tolerances, increasing the final cost of the structure and putting on the edge the reliability of the entire design process.

Currently, imperfection sensitive shell structures prone to buckling are designed according to the NASA SP-8007 guideline, dating from 1968, using its conservative lower bound curve. In this guideline the structural behaviour of composite materials is not appropriately considered, since the imperfection sensitivity and the buckling load of shells made of such materials depend among other things on the lay-up design as well. In this context, a numerical investigation about the different methodologies to characterize the behaviour of imperfection sensitive composite structures subjected to compressive loads up to buckling is presented. A benchmark test is developed using a 500 mm diameter unstiffened composite cylindrical shell. A series of non-linear analyses considering geometric and thickness imperfection, obtained from real measurements, are carried out to characterize the knock-down factor of the benchmark test. The effect of each type of imperfection on the knock-down factor is compared against the experimental results.

ABSTRACT: Large scatter characterizes the collapse load of thin-walled structures due to their imperfection sensitivity. Random fields can be used to include imperfections in a finite element model. Principal component analysis and analytical covariance functions are matched to available correlation information of geometrical imperfection measurements. The random fields are realized by Karhunen-Loève expansion combined with Monte Carlo methods. The results of the different covariance models are compared with the deterministic collapse loads of the measured imperfections in the FE-model. This approach isolates the effect of the different covariance models from other inaccuracies such as boundary conditions, loading imperfections, etc. The results show that random fields models can improve predictions and the understanding of the structural behavior of thin-walled structures, especially by using data based PCA. Caution is recommended with regard to analytical covariance functions since they may fail to capture the complete behavior of the structure.

ABSTRACT: The novel methodology for imperfection sensitivity analysis, presented in Barbero et al.\(^1\) is here applied for the evaluation of limit load of composite cylindrical shells. Koiter’s perturbation method is used to calculate the imperfection paths emanating from mode interaction bifurcations and the Monte Carlo method is used to test a large number of modes and all possible interactions among them. The computational cost is low because of the efficiency of Koiter’s method. The demands of Koiter’s method for accurate evaluations of higher order derivatives of the potential energy are met by a mixed, corotational element.

ABSTRACT: This paper presents the numerical implementation and illustrates the application and potential of a nonlinear elastic generalised beam theory (GBT) beam finite formulation to analyze the postbuckling behavior of laminated CFRP composite thin-walled prismatic cylindrical panels. This formulation (i) is based on a novel GBT cross-section analysis approach, (ii) accounts for the presence of initial geometrical imperfections and (iii) adopts an incremental iterative solution procedure employing the Newton–Raphson method and an arclength control strategy. No stiffness degradation or ply failure is taken into consideration and the material is deemed linear elastic and orthotropic. Numerical results concerning the local buckling and postbuckling behavior of stiffened CFRP cylindrical panels are presented and discussed — one of these panels was experimentally tested and numerically investigated in the context of the COCOMAT project. Taking full advantage of the GBT unique modal features, one is able to (i) examine the nature of the panel structural response, which is expressed in terms of deformation mode participations, and (ii) perform analyses involving very few d.o.f. (by preselecting a small set of deformation modes). The panel buckling loads and deformed configurations obtained from the GBT analyses are validated through comparison with either experimental data or values yielded by shell finite element analyses carried out in the code ABAQUS. In order to assess how the curvature affects the panel buckling and initial postbuckling behavior, a stiffened plate having a width identical to the cylindrical panel is also analyzed and the results obtained are compared with those determined for the corresponding curved panels.

Abstract: Unstiffened composite cylindrical shells show a large scatter in the load levels that the structure can withstand before buckling occurs. Such scatter is greatly influenced by the unavoidable imperfections of the structure, introduced during the fabrication phase. It is thus of key importance to be able to accurately model such imperfections in a numerical computation, in order to recreate and predict the scatter shown in experimental buckling tests. The imperfections can be analyzed by means of random fields, inferring their statistical properties from available measurements. In this manuscript, evolutionary spectra are used to derive random fields of surface and material imperfections of cylindrical shells. A procedure based on a moving window averaging technique is proposed in order to accurately capture the variation of material properties due to imperfect thickness and laminate manufacturing. Finally, Monte Carlo simulations of compression and torsional buckling of cylinders are carried out to show the combined effect of surface and thickness imperfections in the scatter of the buckling limit load.

Furthermore, a series of Finite Element Modeling (FEM) variation of the first natural frequency of vibration with the applied compressive load was measured up to the buckling load of the grid stiffened composite cylindrical shells loaded in compression. Three specimens were fabricated using a new silicone rubber mold, and special silicone rubber mold, and specially-designed filament winding setup. The modal behavior of the grid-stiffened composite cylindrical shells was investigated by exciting the structures using modal hammer method in different applied compression load. Then, the variation of the first natural frequency of vibration with the applied compressive load was measured up to buckling during testing. Furthermore, a series of Finite Element Models (FEMs), including nonlinear effects.
such as geometric and thickness imperfection, are carried out in order to characterize the variation of the natural frequencies of vibration with the applied load and also compare it with the experimental results. Finally, the buckling test was performed to validate the experimental and numerical results of VCT approach. The results showed that the difference between the predicted buckling load using the VCT approach on the experimental results and numerical results with an experimental buckling load is 3.1% and 5.0%, respectively. Also, the current VCT approach has a very good correlation for grid-stiffened composite cylindrical shells when the maximum applied load is higher than 68% of the experimental buckling load.

ABSTRACT: The paper present a discussion related to the use of the “Single perturbation Load Approach” (SPLA) as a methodology to represent geometric imperfection of imperfection sensitive shell structures prone to buckling. In this context, the paper compares the effect of the SPLA on the buckling load of composite cylindrical shells against an alternative methodology, which combines several perturbation loads in different positions, called “Multiple Perturbation Load Approach”. The aim of this paper is to investigate if the SPLA is the worst geometrical imperfection case scenario to be used for finite element simulation. Since the paper is based on experimental results, a benchmark case is developed using a composite cylindrical shell with a radius over thickness ratio of 400. The results of buckling load using one, two and three perturbation loads distributed along the surface of the cylinder shown that the less conservative knock-down factors are obtained by using SPLA.

ABSTRACT: Thin-walled cylindrical composite shell structures can be applied in space applications, looking for lighter and cheaper launcher transport system. These structures are prone to buckling under axial compression and may exhibit sensitivity to geometrical imperfections. Today the design of such structures is based on NASA guidelines from the 1960’s using a conservative lower bound curve generated from a database of experimental results. In this guideline the structural behavior of composite materials may not be appropriately considered since the imperfection sensitivity and the buckling load of shells made of such materials depend on the lay-up design. It is clear that with the evolution of the composite materials and fabrication processes this guideline must be updated and / or new design guidelines investigated. This need becomes even more relevant when cutouts are introduced to the structure, which are commonly necessary to account for access points and to provide clearance and attachment points for hydraulic and electric systems. Therefore, it is necessary to understand how a cutout with different dimensions affects the buckling load of a thin-walled cylindrical shell structure in combination with other initial geometric imperfections. In this context, this paper present some observations regarding the buckling load behavior vs. cutout size and radius over thickness ratio, of laminated composite curved panels and cylindrical shells, that could be applied in further recommendations, to allow identifying when the buckling of the structure is dominated by the presence of the cutout or by other initial imperfections.

ABSTRACT: Structural stability is an important design consideration for launch-vehicle shell structures and it...
is well known that the buckling response of such shell structures can be very sensitive to small geometric imperfections. As part of an effort to develop new buckling design guidelines for sandwich composite cylindrical shells, an 8-ft-diameter honeycomb-core sandwich composite cylinder was tested under pure axial compression to failure. The results from this test are compared with finite-element-analysis predictions and overall agreement was very good. In particular, the predicted buckling load was within 1% of the test and the character of the response matched well. However, it was found that the agreement could be improved by including composite material nonlinearity in the analysis, and that the predicted buckling initiation site was sensitive to the addition of small bending loads to the primary axial load in analyses.

ABSTRACT: A multi-objective Optimality Criteria (OC) is used to obtain optimum design of metal cylindrical shells under combined external loading. The objectives are to maximize the axial and hoop stiffness and minimize the mass of stiffened cylinders subject to the constraints, including functions of weight and buckling load, in such a way that the stiffened shell has no increase in weight and no decrease in buckling load, with respect to the initial unstiffened shell. The optimization process contains six design variables, including shell thickness, number of circular ring stiffeners, number of longitudinal stringer stiffeners, height of ring stiffeners, width of ring stiffeners, and longitudinal stiffener eccentricity from the shell centerline. In the analytical
solution, the Rayleigh-Ritz energy procedure is applied and the ring stiffeners are treated as discrete elements. The shapes of the ring and stringer stiffeners are assumed rectangular and Z, respectively. The shell is subjected to uniform axial and non-constant external pressure, simultaneously. The longitudinal stringers are placed in equal spacing, whereas the rings can be placed in an unequal space, due to the non-constant of external pressure over the cylinder length. The results show that the iteration numbers depend on the ring stiffener space states.

Chiara Bisagni, Potito Cordisco, Haim Abramovich and Tanchum Weller, “Cyclic buckling tests of CFRP curved panels”, 25th International Congress of the Aeronautical Sciences (ICAS), 2006

ABSTRACT: Experimental results obtained on three carbon fibre composite stiffened curved panels subjected to static and cyclic compression and shear loadings are presented. The results obtained from static tests performed on two panels are described in terms of global axial load vs. shortening curve, torque vs. rotation curve, and strain measurements.

A third panel was subjected to a cyclic loading, at 2 Hz, from above zero till 1.6 times its static buckling load, allowing the investigation of the effect of cyclic buckling in terms of axial load vs. shortening behaviour and strain measurements.

The obtained results show that this kind of structures can well work in the post-buckling field even if during their operative life the buckling load is reached thousands of times.

Richard Degenhardt, Jan Tessmer and Alexander Kling, “Collapse behaviour of thin-walled CFRP structures due to material and geometric nonlinearities – Experiments and simulation”, 26th International Congress of the Aeronautical Sciences (ICAS), 2008

ABSTRACT: Aerospace industry strives for significantly reduced development and operating costs. Reduction of structural weight at safe design is one possibility to reach this objective. Another one is the use of reliable simulation methods in order to minimize expensive and time consuming experimental design studies. DLR has developed improved concepts and tools for fast and reliable simulation of the buckling and the postbuckling behaviour of thin-walled structures up to collapse, respectively, which allow the exploitation of considerable reserves in primary fibre composite structures in aerospace applications [1-4]. For the validation of these concepts and tools, a sound database of experiments is needed. Such has grown considerably through many recent projects (e.g. EU-“COCOMAT” [5,6], EU-“POSICOSS”, ESA-“Probabilistic Aspects of Buckling Knock Down Factors — Tests and Analysis”, etc.). The paper presents first the experimental activities at the buckling test facility of the DLR Institute of Composite Structures and Adaptive Systems with an overview about buckling, postbuckling and collapse tests in combination with advanced measurement systems. Secondly, suitable computational methods are presented.

ABSTRACT: Adopting composite aero structures at safe design to operate in the postbuckling state, between the design limit and ultimate loads and possibly even below the design limit load, can potentially lead to significantly lighter aero structures. For this reason the research field related with buckling and postbuckling design, analysis and tests has drawn great attention and obtained some research achievements in current years. However, it is still difficult to predict the buckling and postbuckling strength of these structures.

The first part of the research consists in the design, manufacturing, measuring and testing of single stringer composite specimens. The specimens are in carbon fibers reinforced plastics, and consist of a skin panel with one stiffener, where the L-shaped stiffener is co-cured with the skin. The design is performed with numerical analysis using the finite element code ABAQUS to investigate the buckling and post buckling field under static compression. The tests are then performed under axial compression, where the compression load leads the panels to buckle.

The second part of the research consists in the study of the damage, including the damage modes as well as the damage propagation. Indeed, the out-of-plane deformation due to buckling causes progressive damage propagation. The results of the numerical analysis are compared to the experimental ones in terms of load-shortening curves, post-buckling shapes and progressive damage propagation.

ABSTRACT: In this work, a recently proposed nonlocal theory of bending is used in the analysis of eigenfrequencies of single-walled carbon nanotubes (SWCNTs). The nanotube vibration is analyzed in the form of a homogenized continuum. Classical treatment where a nanotube is approximated by standard beam theory, is replaced by the more sophisticated nonlocal method of material interactions where a nonlocal parameter is used. The eigenfrequencies are computed by the combination of analytical as well as numerical methods for four different carbon nanotube (CNT) supports. Various types of supports are considered for the analysis: fixed–simply supported, fixed–free, simply–simply supported and fixed–fixed. Due to the huge amount of computed data, only outcomes of eigenfrequency computations for the nanobeams of armchair type with fixed and simply supported ends, and different nonlocal parameters are represented in the form of graphs at the end of the article. The study shows how the nanotube eigenfrequencies depend on nonlocal parameters as well as on the length and diameter of CNTs. The obtained results are in good agreement with the results published in papers which were gained by different procedures.

ABSTRACT: An Element Free Galerkin Method (EFGM) for the analysis of degenerated shell structures is presented. The method is based on the Moving Kriging (MK) Interpolation function. The properties of the interpolation function possess the Kronecker delta property. With the MK Interpolation function no additional treatment required at the boundary conditions compared with that of using Moving Least Square (MLS) approximation. This deficiency of MLS at boundary condition has been definitely eradicated. The membrane and shear locking in the numerical analysis for degenerated shell problems has been alleviated by using higher order and removed by using quartic order of polynomials. Numerical benchmark examples for shell structures are presented to validate the proposed approach.

Defects in composite materials are created during manufacture to a large extent. To avoid them as much as possible, it is important that process simulations model the onset and the development of these defects. It is then possible to determine the manufacturing conditions that lead to the absence or to the controlled presence of such defects. Three types of defects that may appear during textile composite reinforcement or prepreg forming are analysed and modelled in the present paper. Wrinkling is one of the most common flaws that occur during textile composite reinforcement forming processes. The influence of the different rigidities of the textile reinforcement is studied. The concept of ‘locking angle’ is questioned. A second type of unusual behavior of fibrous composite reinforcements that can be seen as a flaw during their forming process is the onset of peculiar "transition zones" that are directly related to the bending stiffness of the fibers. The ‘transition zones’ are due to bending stiffness of fibres. The standard continuum mechanics of Cauchy is not sufficient to model these defects. A second gradient approach is presented that allows to account for such unusual behaviors zones' are due to bending onsets and developments during forming processes. Finally the large slippages that may occur during a preform forming are discussed and simulated with meso F.E. models used for macroscopic forming processes. It may occur during a preform forming are discussed and simulated with meso F.E. models used for macroscopic forming processes. 33. Sharma SB, Sutcliffe MPF, Chang SH. Characterisation of material properties for draping of dry woven composite material. Compos Part A 2003;34:1167–75.

ABSTRACT: Experimental testing on dry woven fabrics exhibits a complex set of evidences that are difficult to be completely described using classical continuum models. The aim of this paper is to show how the introduction of energy terms related to the micro-deformation mechanisms of the fabric, in particular to the bending stiffness of the yarns, helps in the modeling of the mechanical behavior of this kind of materials. To
this aim, a second gradient, hyperelastic, initially orthotropic continuum theory is proposed to model fibrous composite interlocks at finite strains. In particular, the present work explores the relationship between the onset of wrinkling appearing during the simulation of the deep drawing of a woven fabric and the use of a second gradient model. It is shown that the introduction of second gradient terms accounting for the description of in-plane and out-of-plane bending rigidities, decreases the onset of wrinkles during the simulation of deep-drawing. In this work, a quadratic energy, roughly proportional to the square of the curvature of the fibers, is presented and implemented in the simulations. This simple constitutive assumption allows to clearly show the effects of the second gradient energy on both the wrinkling description and the numerical stability of the model. The results obtained in second gradient simulations are descriptive of the experimental evidence of deep drawing whose description is targeted in this work. The present paper provides additional evidence of the fact that first gradient continuum theories alone cannot be considered fully descriptive of the behavior of dry woven composite reinforcements. On the other hand, the proposed second gradient model for fibrous composite reinforcements opens the way both to the more accurate simulation of complex forming processes and to the possibility of controlling the onset of wrinkles.

ABSTRACT: We propose two toy-models to describe, predict, and interpret the wrinkles appearing on the surface of skin when it is sheared. With the first model, we account for the lines of greatest tension present in human skin by subjecting a layer of soft tissue to a pre-stretch, and for the epidermis by endowing one of the layer’s faces with a surface tension. For the second model, we consider an anisotropic model for the skin, to reflect the presence of stiff collagen fibres in a softer elastic matrix. In both cases, we find an explicit bifurcation criterion, linking geometrical and material parameters to a critical shear deformation accompanied by small static wrinkles, with decaying amplitudes normal to the free surface of skin.

ABSTRACT: Six laboratory scale, mild steel pipes with the outside diameter-to-wall-thickness ratio, D/t about
40, were dented to about 15–20% of outside diameter $D_o$, by a hemispherical indenter with its diameter to pipe’s outside diameter ratio, $2a/D_o$ about 0.41. Three pipes had surface gouges running axially in them, and the remaining three were gouge free. Five of them were then collapsed by a bending moment followed by pressure burst tests. Experimental test data has been used to benchmark the finite element results, details of which are given in this paper. Good agreement between experimental and numerical results was obtained in the modeling of denting, but not so well in the modeling of bending — indicating the need for further work in order to address the discrepancies. these structural behaviours of beams and plates at both micro- and macro- scales using the variational principle. Numerical results are computed using MATLAB and verified with the published results to demonstrate the accuracy and efficiency of the developed theoretical formulation. The numerical applications include: 1. the free vibration and buckling behaviours of FG and FG sandwich macrobeams under arbitrary boundary conditions and mechanical/thermal loads, 2. the static, free vibration and buckling behaviours of simply supported FG microbeams, and the free vibration behaviour of bidirectional FG microbeams under arbitrary boundary conditions, 3. the static, free vibration and buckling behaviours of simply supported FG-sandwich microplates under mechanical/thermal loads, and 4. the static, free vibration and buckling behaviours of FG-sandwich microplates with two opposite simply supported edges and various boundary conditions for other edges. The outcomes from this thesis emphasize the need of including couple stress in analyzing the structural behaviours of FG beams and plates at microscales. Some of them are presented at the first time and can be used as the benchmark results for numerical methods. These analytical methods can also be combined with other strong form methods to analyse various types of complex structures.

ABSTRACT: With increasing size of wind turbines, new approaches to load control are required to reduce the stresses in blades. Experimental and numerical studies in the fields of helicopter and wind turbine blade research have shown the potential of shape morphing in reducing blade loads. However, because of the large size of modern wind turbine blades, more similarities can be found with wing morphing research than with helicopter blades. Morphing technologies are currently receiving significant interest from the wind turbine community because of their potential high aerodynamic efficiency, simple construction and low weight. However, for actuator forces to be kept low, a compliant structure is needed. This is in apparent contradiction to the requirement for the blade to be load carrying and stiff. This highlights the key challenge for morphing structures in replacing the stiff and strong design of current blades with more compliant structures. Although not comprehensive, this review gives a concise list of the most relevant concepts for morphing structures and materials that achieve compliant shape adaptation for wind turbine blades.

ABSTRACT: The loads on wind turbine components are primarily from the blades. It is important to control these loads in order to avoid damaging the wind turbine. Rotor control technology is currently limited to controlling the rotor speed and the blade pitch. As blades increase in length, it becomes less desirable to pitch the entire blade as a single rigid body, but there is a requirement to control loads more precisely along the length of the blade. This can be achieved with aerodynamic control devices such as flaps. Morphing structures are good candidates for wind turbine flaps because they have the potential to create structures that have the conflicting abilities of being load carrying, lightweight and shape adaptive. A morphing flap design with an anisotropic cellular structure is presented, which is able to undergo large deflections and high strains. An aeroelastic analysis couples the work done by aerodynamic loads on the flap, the flap strain energy and the required actuation work to change shape. The morphing flap model is manufactured, and its stiffness is measured.

ABSTRACT: This work presents the results of 21 shear tests on three types of honeycomb cores: the HRH-78-3/16-3.0, HRH-10-3/16-6.0 and an aluminium honeycomb core made of 5052 alloy with 3/8” cells. First, a benchmark of the different designs for shear testing of the honeycomb cores is made. Then, several double lap specimens were fabricated and tested while a 3D image correlation system was used to record the tests. An experimental analysis of the post-buckling phenomena of the HRH-78 W is presented. An artificial neural network is developed and used to visually identify the buckles of the test specimens. Finally, a detailed description of the behaviour of the structure including the postbuckling scenario is presented.

ABSTRACT: In this study, we develop a model to describe the free vibration behavior of a cracked nanobeam embedded in an elastic medium by considering the effects of longitudinal magnetic field and temperature change. In order to take into account the small-scale and thermal effects, the Euler-Bernoulli beam theory based on the nonlocal elasticity constitutive relation is reformulated for one-dimensional nanoscale systems. In addition, the effect of a longitudinal magnetic field is introduced by considering the Lorenz magnetic force obtained from the classical Maxwell equation. To develop a model of a cracked nanobeam, we suppose that a nanobeam consists of two segments connected by a rotational spring that is located in the position of the cracked section. The surrounding elastic medium is represented by the Winkler-type elastic foundation. Influences of the nonlocal parameter, stiffness of rotational spring, temperature change and magnetic field on the system frequencies are investigated for two types of boundary conditions. Also, the first four mode shape functions for the considered boundary conditions are shown for various values of the crack position.

ABSTRACT: The presented paper deals with the analysis of energy transfer in the visco-elliastically connected circular double-membrane system for free transverse vibration of the membranes. The system motion is described by a set of two coupled non-homogenous partial differential equations. The solutions are obtained by using the method of separation of variables. Once the problem is solved, natural frequencies and mode shape functions are found, and then the form of solution for small transverse deflections of membranes is derived.

Using the obtained solutions, forms of reduced kinetic, potential and total energies, as functions of dissipation of the whole system and subsystems, are determined. The numerical examples are given as an illustration of the presented theoretical analysis as well as the possibilities to investigate the influence of different parameters and different initial conditions on the energies transfer in the system.

ABSTRACT: We use the incremental harmonic balance (IHB) method to analyse the dynamic stability problem of a nonlinear multiple-nanobeam system (MNBS) within the framework of Eringen’s nonlocal elasticity theory. The nonlinear dynamic system under consideration includes MNBS embedded in a viscoelastic medium as clamped chain system, where every nanobeam in the system is subjected to time-dependent axial loads. By assuming the von Karman type of geometric nonlinearity, a system of m nonlinear partial differential equations of motion is derived based on the Euler–Bernoulli beam theory and D’Alembert’s principle. All nanobeams in MNBS are considered with simply supported boundary conditions. Semi-analytical solutions for time response functions of the nonlinear MNBS are obtained by using the single-mode Galerkin discretization and IHB method, which are then validated by using the numerical integration method. Moreover, Floquet theory is employed to determine the stability of obtained periodic solutions for different configurations of the nonlinear MNBS. Using the IHB method, we obtain an incremental relationship with the frequency and amplitude of time-varying axial load, which defines stability boundaries. Numerical examples show the effects of different physical and material parameters such as the nonlocal parameter, stiffness of viscoelastic medium and number of nanobeams on Floquet multipliers, instability regions and nonlinear amplitude–frequency response curves of MNBS. The presented results can be useful as a first step in the study and design of complex micro/nanoelectromechanical systems.

ABSTRACT: In this investigation, a continuum mechanics based shear deformable shell element of the absolute nodal coordinate formulation (ANCF) is generalized to a laminated shell element for application to the modeling of fiber-reinforced rubber (FRR) structure of the physics-based ANCF tire model. The complex deformation coupling exhibited in fiber-reinforced composite materials can be automatically considered in the shear deformable laminated shell element using the continuum mechanics approach, and the element lockings are systematically eliminated by the assumed natural strain and enhanced strain approaches, thereby leading to a locking-free shear deformation ANCF laminated shell element. Furthermore, various nonlinear material models can be considered for each layer in a way same as solid elements. Using the ANCF laminated shell element developed, a physics-based ANCF tire model is developed by considering the detailed tire geometry and
material properties. The experimental validation of the tire model is conducted for the load-deflection curve to ensure that the fundamental structural tire properties can be correctly captured in the ANCF tire model. References listed at the end of the paper:

ABSTRACT: A high-fidelity physics-based deformable tire-soil interaction model that can be fully integrated into multibody dynamics computer algorithms is developed for use in off-road mobility simulation. To this end, the finite-element (FE) tire simulation capability based on the flexible multibody dynamics approach, which allows for modeling the coupling of the structural tire dynamics and transient tire friction under hard braking and concerning maneuvers, is further extended to off-road mobility simulations. A locking-free nine-node brick element is developed by introducing an additional center node to the standard 8-node brick element, which defines the second derivative of the global position vector at this node, to alleviate the element lockings without special techniques such as the enhanced assumed strain approach. This allows for a straightforward implementation of the multiplicative finite strain plasticity theory along with the capped Drucker-Prager failure criterion to model the large plastic soil deformation exhibited as sinkage on deformable terrains. The tire-soil interaction model is fully integrated into the monolithic multibody dynamics computer algorithm to ensure the accuracy and numerical stability under transient vehicle maneuvers. In order to identify soil parameters including cohesion and friction angle, the triaxial soil test is carried out, and the soil model developed is validated against the test data. Use of the high-fidelity physics-based tire-soil simulation model in off-road mobility simulations, however, leads to a very large computational model to consider a wide range of terrains. Thus, the computational cost dramatically increases as the size of the soil model increases. To address this issue, the moving soil patch technique is applied such that the soil behavior only in the vicinity of the rolling tire is solved to reduce the model dimensionality associated with the finite-element soil model. It is shown that use of
this approach leads to a significant reduction in computational time while ensuring the accuracy. Finally, the proposed off-road tire-soil simulation capability is validated against test data obtained from a soil bin mobility test facility, including the effect of wheel loads and tire inflation pressures on the longitudinal/cornering tire forces and the rolling resistance.

ABSTRACT: Assessing the mobility of off-road vehicles is a complex task that most often falls back on semi-empirical approaches to quantifying the vehicle–terrain interaction. Herein, we concentrate on physics-based methodologies for wheeled vehicle mobility that factor in both tire flexibility and terrain deformation within a fully three-dimensional multibody system approach. We represent the tire based on the absolute nodal coordinate formulation (ANCF), a nonlinear finite element approach that captures multi-layered, orthotropic shell elements constrained to the wheel rim. The soil is modeled as a collection of discrete elements that interact through contact, friction, and cohesive forces. The resulting vehicle/tire/terrain interaction problem has several millions of degrees of freedom and is solved in an explicit co-simulation framework, built upon and now available in the open-source multi-physics package Chrono. The co-simulation infrastructure is developed using a Message Passing Interface (MPI) layer for inter-system communication and synchronization, with additional parallelism leveraged through a shared-memory paradigm. The formulation and software framework presented in this investigation are proposed for the analysis of the dynamics of off-road wheeled vehicle mobility. Its application is demonstrated by numerical sensitivity studies on available drawbar pull, terrain resistance, and sinkage with respect to parameters such as tire inflation pressure and soil cohesion. The influence of a rigid tire assumption on mobility is also discussed.

“Bending behavior of regularly spaced CLT panels”, World Conference on Timber Engineering (WCTE 2016), Vienna, Austria, August 22-25, 2016

ABSTRACT: A regular alternation of lamellas and voids filled by insulating material within each layer of CLT [Cross Laminated Timber] can lead to cellular panels with improved acoustical, thermal and fire performance. In order to support the development of these innovative and lighter engineered wood products, their mechanical behavior is investigated in this paper by means of experiments and modeling. First, an experimental campaign
on spaced CLT panels and related results are presented. Then, both simplified and refined modelings are applied. The chosen accurate modeling is a periodic homogenization scheme handled by a plate theory [1] and based on unit-cell strain energy computation with FEM. It appears that the simplified approach can predict the bending stiffness (EI) of CLT panels with large voids but not their transverse shear stiffness (GA) which can be precisely predicted with the more refined modeling. Finally, the influence of several panel’s parameters on the mechanical response is pointed out as well.

**ABSTRACT:** Finite element analysis is used to model the automatic cambering of the locust hind wing during promotion: the umbrella effect. It was found that the model required a high degree of sophistication before replicating the deformations found in vivo. The model has been validated using experimental data and the deformations recorded both in vivo and ex vivo. It predicts that even slight modifications to the geometrical description used can lead to significant changes in the deformations observed in the anal fan. The model agrees with experimental data and produces deformations very close to those seen in free-flying locusts. The validated model may be used to investigate the varying geometries found in orthopteran anal fans and the stresses found throughout the wing when loaded.

ABSTRACT: Cold-formed built-up members are compression members that are common in multiple areas of steel construction, which include cold-formed steel joints and stud walls. These members are vulnerable to unique buckling behaviors; however, limited experimental research has been done in this area. Give this gap, experimental testing of 71 built-up members was conducted in this study. The variations of the test specimens include multiple lengths, intermediate welds, orientations, and thicknesses. The experimental testing was devised to observe the different buckling modes of the built-up C-channels and the effects of the geometrical properties; to check for applicability of multiple intermediate welding patterns; and to evaluate both the 2001 and 2007 editions of the American Iron and Steel Institute (AISI) Specification for built-up members in pure compression. The AISI-2001 and AISI-2007 were found to give inconsistent results that at times were un-conservative or overly conservative in terms of axial strength. It was also found that orientation of the member has an important impact on the maximum failure load on the member.

ABSTRACT: In the present paper, the aero-thermo-elastic behavior of a finite (three-dimensional) cylindrical curved panel geometry made from functionally graded material under high supersonic airflow is investigated. A generalized differential quadrature formulation is adopted while a steady-state through-the-thickness thermal field is also assumed. The geometry curvature and structural nonlinearity effects are included based on von Karman–Donnell strain–displacement relations. The nonlinear piston theory of third order is utilized in order to predict the unsteady aerodynamics loads induced from surrounding supersonic air stream. The functionally graded material is considered with temperature-dependent properties distributed in the thickness according to a power law function. Derived from the equilibrium equations, the aero-thermo-elastic governing equations are reduced to number of ordinary differential equations through using of the generalized differential quadrature method where the structure response is derived using fourth-order Runge–Kutta technique. The contribution of some parameters including flow Mach number, flow dynamic pressure, thickness temperature gradient, and functionally graded material volume fraction index on the flutter response as well as route-to-chaos behavior are reviewed. The calculated results are compared with those available in the literature wherever available and the accuracy and quality of the adopted generalized differential quadrature formulation in analyzing the aero-thermo-elastic behavior of three-dimensional functionally graded curved panels is shown. It reveals that using a three-dimensional approach, if any of Mach number and panel’s upper surface temperature is increased, the route-to-chaos behavior is reached through quasi-periodic motions.

ABSTRACT: A design procedure is presented to estimate the load carrying capacity of beam-column channel sections. A reduced cross-section is used to compensate for the reduction in the post-buckling stiffness. The non-linear stress distribution acting on the entire channel width is replaced by simplified linear distributions. Using this simplified concept, the maximum stress in the post-buckling state, is assumed to be carried entirely by both edges while the central region of the channel remains unstressed. Thus a fraction of the channel section is considered in resisting the applied loading. This approximation enables the structural engineer to deal with a simplified stress distribution to compute the ultimate strength instead of the non-linear one.

ABSTRACT: We investigate theoretically and experimentally the nonlinear responses of a clamped-clamped buckled beam to a variety of external harmonic excitations and internal resonances. We assume that the beam geometry is uniform and its material is homogeneous. We initially buckle the beam by an axial force beyond the critical load of the first buckling mode, and then we apply a transverse harmonic excitation that is uniform over its span. The beam is modeled according to the Euler-Bernoulli beam theory and small strains and moderate rotation approximations are assumed. We derive the equation of motion governing the nonlinear transverse planar vibrations and associated boundary conditions using the extended Hamilton’s principle. The governing equation is a nonlinear integral-partial-differential equation in space and time that possesses quadratic and cubic nonlinearities. A closed-form solution for such equations is not available and hence we seek approximate solutions.

We use perturbation methods to investigate the slow dynamics in the neighborhood of an equilibrium configuration. A Galerkin approximation is used to discretize the nonlinear partial-differential equation governing the beam’s response and obtain a set of nonlinearly coupled ordinary-differential equations governing the time evolution of the response. We based our theory on a multi-mode Galerkin discretization. To investigate the large-amplitude dynamics, we use a shooting method to numerically integrate the discretized equations and obtain periodic orbits. The stability and bifurcations of these periodic orbits are investigated using Floquet theory.

We solve the nonlinear buckling problem to determine the buckled configurations as a function of the applied axial load. We compare the static buckled configurations obtained from the discretized equations with the exact ones. We find out that the number of modes retained in the discretization has a significant effect on these static configurations. We consider three cases: primary resonance, subharmonic resonance of order one-half of the first vibration mode, and one-to-one internal resonance between the first and second modes. We obtain interesting dynamics, such as phase-locked and quasiperiodic motions, resulting from a Hopf bifurcation, snapthrough motions, and a sequence of period-doubling bifurcations leading to chaos.

To validate our theoretical results, we ran an experiment, which is a modified version of the experiment designed by Kreider and Nayfeh. We find that the obtained theoretical results are in good qualitative agreement with the experimental results. In the case of one-to-one internal resonance, we report, theoretically and experimentally, energy transfer between the first mode, which is externally excited, and the second mode.

ABSTRACT: We introduce an intuitive method, called Marionette, for the modelling of free-form architecture with planar facets. The method takes inspiration from descriptive geometry and allows to design complex shapes with one projection and the control of elevation curves. The proposed framework achieves exact facet planarity in real time and considerably enriches previous geometrically constrained methods for free-form architecture. A discussion on the design of quadrilateral meshes with a fixed horizontal projection is first proposed, and the method is then extended to various projections and patterns. The method used is a discrete solution of a continuous problem. This relation between smooth and continuous problem is discussed and shows how to combine the marionette method with modelling tools for smooth surfaces, like non-uniform rational basis spline or T-splines. The result is a versatile tool for shape modelling, suited to engineering problems related to free-form architecture.

ABSTRACT: The last decades have seen the emergence of non-standard architectural shapes. Designers find themselves helpless with the geometrical complexity of these objects. Furthermore, the available tools dissociate shape and structural behaviour, which adds another complication. This dissertation takes the point of view based on invariance under geometrical transformations, and studies several strategies for fabrication-aware shape modelling. Three technological constraints have been identified and correspond to three independent contributions of this thesis.

The repetition of nodes is studied via transformations by parallelism. They are used to generalise surfaces of revolution. A special parametrisation of moulding surfaces is found with this method. The resulting structure has a high node congruence.

Cyclidic nets are then used to model shapes parametrised by their lines of curvature. This guarantees meshing by planar panels and torsion-free beam layout. The contribution of this dissertation is the implementation of several improvements, like doubly-curved creases, a hole-filling strategy that allows the extension of cyclidic nets to complex topologies, and the generation of a generalisation of canal surfaces from two rail curves and one profile curves.

Finally, an innovative method inspired by descriptive geometry is proposed to generate doubly-curved shapes covered with planar facets. The method, called marionette technique, reduces the problem to a linear problem, which can be solved in real-time. A comparative study shows that this technique can be used to parametrise shape optimisation of shell structures without loss of performance compared to usual modelling technique. The handling of fabrication constraints in shape optimisation opens new possibilities for its practical application, like gridshells or plated shell structures. The relevance of those solutions is demonstrated through multiple case-studies.

INTRODUCTION: Les couvertures de bâtiment sont des structures spécifiques, leur chargement principal est en général leur propre poids. Chercher à concevoir ces structures les plus légères possible permet des avancées économiques, écologiques et esthétiques. Les méthodes constructives ont évoluées avec les époques et les matériaux disponibles, mais toujours autour de trois axes principaux : l’adaptation de la forme et du matériau, l’utilisation de la double courbure et la minimisation des efforts de flexion. C’est en cherchant à s’affranchir complètement des efforts de flexion sous poids propre que Frei Otto a développé les structures de gridshells. Ces coques discrètes à double courbure résultent de l’inversion d’un filet suspendu, elles sont donc les exacts funiculaires de leur propre poids. De plus, il met au point un procédé constructif original et très économique qui permet d’obtenir des surfaces gauches par déformation élastique et triangulation d’une grille plane sans rigidité en cisaillement et constituée d’éléments rectilignes standard. Après quelques réalisations mineures, le potentiel esthétique et mécanique de ces structures éclate avec la construction du gridshell de Mannheim en 1975. Pourtant le bâtiment ne fait pas école et reste pendant vingt-cinq ans le seul gridshell au monde, malgré des qualités remarquables sur le plan structurel. Deux raisons principales seront avancées pour expliquer cette situation : d’une part les méthodes de calcul de l’époque négligent la flexion dans les éléments et par conséquent ne permettent pas d’étudier précisément les contraintes dans la structure et d’autre part, les éléments
de la grille sont en bois lamellé-collé et leur état de flexion permanente pose des problèmes de fluage et de durabilité des assemblages. Dans le premier chapitre, après un historique des gridshells, on verra que les progrès de ces dernières années en matière de simulation numérique et les efforts de la filière bois pour rationaliser les profils ont permis un renouveau de ces structures en Angleterre avec les gridshells du musée de Downland et du Savill Building.

Il semble cependant possible d’aller plus loin dans cette rationalisation en proposant des solutions alternatives plus durables et plus performantes qui intègrent des nouveaux matériaux fibrés synthétiques en lieu et place de ce matériau composite anisotrope naturel qu’est le bois. Les polymères renforcés de fibres de verre ou de carbone sont relativement nouveaux dans le génie civil et la construction. Leurs applications actuelles copient les solutions techniques qui ont été optimisées pour l’acier (armature pour béton, renforcement par collage, poutrelle en I ou en H, etc.). Beaucoup plus souples que l’acier, les composites apparaissent rarement comme la solution la plus pertinente pour ces applications dans lesquelles les exigences de raideur conduisent à un surdimensionnement de la structure en terme de résistance. En revanche, les contraintes constructives des gridshells liées à leur processus de montage utilisent la déformabilité des éléments. Leur allongement élastique important et leur module d’Young élevé font donc des composites de bons candidats pour ce type de structure.

On remarque d’ailleurs que partout où une grande déformabilité et une grande raideur sont exigées en même temps, il s’imposent : ailes de planeur, arcs, skis, cannes à pêche, pare-chocs... Dans le deuxième chapitre, on démontrera donc que les composites verre/ré sine constituent véritablement une alternative intéressante au bois pour la construction des gridshells et on étudiera plus en détail le comportement mécanique de ces matériaux dans les conditions de flexion en grands déplacements qui sont celles des éléments d’un gridshell.

Effectivement, l’amplitude des déplacements qui interviennent durant le montage des gridshells est grande et leur calcul nécessite l’utilisation de méthodes numériques capables de prendre en compte des non-linéarités géométriques. Par le passé, trois méthodes ont été utilisées pour le calcul des gridshells : la méthode des densités de forces, la méthode de Newton-Raphson et la méthode de relaxation dynamique. C’est cette dernière qui a été choisie ici et qui sera exposée dans le troisième chapitre. Son principe consiste à remplacer la recherche de l’état d’équilibre statique par un calcul dynamique fictif qui, par amortissements successifs, va conduire à l’état d’équilibre statique. Les modèles utilisés pour le calcul dynamique et le calcul des efforts intérieurs sont exposés, ainsi qu’un modèle original pour la prise en compte des excentricités au niveau des liaisons. Viennent ensuite l’étude de la stabilité de l’algorithme et sa validation par de nombreuses comparaisons avec d’autres modèles analytiques et numériques, ce qui donnera l’occasion d’illustrer également la polyvalence de la méthode.

À la différence de la plupart des structures à double courbure existantes, la forme des gridshells ne peut pas être imposée : elle est l’unique forme d’équilibre qui satisfait un ensemble donné de contraintes géométriques et de conditions d’appui. La recherche de la forme est donc un enjeu en soi et elle fait l’objet du quatrième chapitre. Trois méthodes sont développées. La première a été systématisée par Frei Otto : elle repose sur l’étude de modèles réduits parfaitement tendus et conduit à des formes dont le contour ou les points d’appui sont imposés. La deuxième consiste l’un des objets de ce travail, elle est indissociable de l’utilisation de la méthode de relaxation dynamique et de la prise en compte de la raideur en flexion des éléments ; elle conduit à des formes dont les contours libres sont l’expression de la raideur naturelle de la matière. La troisième n’est qu’esquissée mais semble très prometteuse pour la conception de structures pour des enveloppes courbes, elle permet de fabriquer des grilles en équilibre sur des surfaces dont la forme est imposée.

Cependant la donnée de la forme ne suffit pas à définir une structure. Il faut bien entendu en étudier le comportement mécanique. Dans le cinquième chapitre, on aborde tout d’abord la question du règlement de construction de référence pour la définition des chargements et des critères de dimensionnement des éléments. Il semble aujourd’hui naturel que cette étude s’inscrive dans le cadre des Eurocodes. Il n’existe pas de tome spécifique dédié aux matériaux composites, mais des coefficients partiels de sécurité et des critères spécifiques ont déjà été proposés et seront examinés ici. À titre d’illustration, ils sont mis en œuvre dans l’étude d’un prototype de gridshell en composites construit à l’École Nationale des Ponts et Chaussées. Cette étude comprend la description des matériaux utilisés et l’identification de leurs propriétés mécaniques, la définition de la forme, l’étude de deux variantes de triangulation et celle du comportement sous chargement réglementaire. Chacune de ces étapes permet de mettre en lumière certains traits spécifiques du comportement des gridshells. Le sixième chapitre décrit la construction de ce prototype et le programme expérimental réalisé en collaboration avec l’École Nationale des Sciences Géographiques. Les différentes étapes du montage et les techniques utilisées sont tout d’abord expliquées, ainsi que les tests de chargement effectués sur la structure avant et après
triangulation. Les résultats de ces tests seront ensuite analysés afin notamment de quantifier l’effet de la triangulation. Ils seront également confrontés à un modèle numérique construit à partir du relevé des positions des appuis de la structure réelle. Cela permettra en outre de mieux comprendre le comportement d’ensemble de la structure et l’évolution des contraintes dans les éléments. Enfin, quelques éléments de bilan sur les coûts de ce prototype sont donnés afin de montrer sa compétitivité par rapport à des structures déjà exploitées industriellement dans la construction.

Le dernier chapitre rappellera les principaux résultats de ce travail et conclura sur l’efficacité des outils proposés pour l’analyse des structures élancées précontraintes en matériaux composites, la pertinence des structures de gridshells pour la réalisation de couvertures de moyenne ou de grande portée. Un dernier mot sera ajouté sur les perspectives de développement du programme et des méthodes, ainsi que sur les nouvelles applications envisageables.

Maheri (Department of Civil Engineering, Shiraz University, Iran), “Soil-structure interaction effects in buried cylindrical concrete structures”, Proceedings of the Tenth International Conference on Civil, Structural and Environmental Engineering Computing, B.H.V. Topping (Editor), Civil-Comp Press, Stirling, Scotland, Paper No. 271, January 2005
ABSTRACT: To design an underground structure against the earthquake or blast loading, the dynamic properties of such structures are often first established. In this paper, a finite element parametric dynamic analysis of the structure-soil system is carried out. The structures considered are cylindrical concrete structures and the main variable parameters include; the radius of the cylindrical structure (R), the ratio of the horizontal extent of the soil to the radius of the structure (L/R), the horizontal width of soil to the radius of the structure (H/R) and the ratio of depth of burial to the radius of the structure (D/R). It is shown that the conventional added-mass approach greatly overestimates the natural frequencies of the soil-structure system and the level of overestimation is more profound for the shallow-buried structures. For the deep-buried structures, the added-mass of soil dominates the response and the effect of the added-stiffness is reduced. Also it is found that the discrepancies in the results of the added-mass solution and the FE solution increase as the structure becomes more flexible.

ABSTRACT: Stiffened thin-walled steel cylinders have been used as compression elements in the field of offshore structures for many years. On-site durability of these structures may suffer from the harsh marine environment. Therefore, a structural health monitoring system that provides real-time structural feedback of the structure is mandatory to ensure the safe operations of an offshore structure. Hence, this study investigates the applicability of a new state-of-the-art methodology, called inverse finite element method (iFEM), for displacement and stress monitoring of offshore structures for the first time in the literature. Displacement and stress solutions obtained from iFEM analysis are compared to those of reference solutions.

ABSTRACT:

Purpose – The purpose of this paper is to optimize a new thin-walled cellular configuration with crashworthiness criteria, so as to improve the crashworthiness of components of a vehicle body.

Design/methodology/approach – ANSYS Parametric Design Language is used to create the parameterized models so that the design variables can be changed conveniently. Moreover, the surrogate technique, namely response surface method, is adopted for fitting objective and constraint functions. The factorial design and D-optimal criterion are employed to screen active parameters for constructing the response functions of the specific energy absorption and the peak crushing force. Finally, sequential quadratic programming-NLPQL is utilized to solve the design optimization problem of the new cellular configurations filled with multi-cell circular tubes under the axial crushing loading.

Findings – Two kinds of distribution modes of the cellular configurations are first investigated, which are in an orthogonal way and in a diamond fashion. After comparing the optimized configurations of the rectangular distribution with the annular distribution of the multi-cell fillers, it is found that the orthogonal way seems better in the aspects of crashworthiness than the diamond fashion.

Originality/value – The two new thin-walled cellular configuration are studied and optimized with the crashworthiness criteria. Study on the new cellular configurations is very valuable for improving the crashworthiness of components of a vehicle body. Meanwhile, the factorial design and the factor screening are adopted in the process of the crashworthiness optimization of the new thin-walled cellular configurations.

ABSTRACT: Foam-filled thin-walled structure has been widely used in vehicle engineering due to its highly efficient energy absorption capacity and lightweight. Unlike the existing foam-filled thin-walled structures, a new foam-filled structure, i.e., functionally graded foam-filled graded-thickness tube (FGFGT), which had graded foam density along the transverse direction and graded wall thickness along the longitudinal direction, was first studied in this paper. Two FGFGTs with different gradient distributions subjected to lateral impact were investigated using nonlinear finite element code through LS-DYNA. According to the parametric sensitivity analysis, we found that the two design parameters n1 and n2, which controlled the gradient distributions of the foam density and the tube wall thickness, significantly affected the crashworthiness of the two FGFGTs. In order to seek for the optimal design parameters, two FGFGTs were both optimized using a meta-model-based multi-objective optimization method which employed the Kriging modeling technique as well as the nondominated sorting genetic algorithm II. In the optimization process, we aimed to improve the specific energy absorption and to reduce the peak crushing force simultaneously. The optimization results showed that the FGFGT had even better crashworthiness than the traditional uniform foam-filled tube with the same weight. Moreover, the graded wall thickness and graded foam density can make the design of the FGFGT flexible. Due to these advantages, the FGFGT was an excellent energy absorber and had potential use as the...

ABSTRACT: As one of the most widely used safety devices on highways, W-beam guardrail plays an important role in protecting errant vehicles from entering dangerous zones or colliding with oncoming vehicles. As one of the most widely used safety devices on highways, W-beam guardrails play an important role in protecting errant vehicles from entering dangerous zones or colliding with oncoming vehicles. One common issue with the traditional W-beam guardrails (TWG) is tire snagging which often occurred when the wheel of a striking vehicle entangled with a guardrail post. Tire snagging reduces the redirection performance of the guardrail and can result in serious injuries to the occupants. In this study, a new W-beam guardrail, named as “η-shaped W-beam guardrail (η-WG)”, was developed using nonlinear finite element simulations combined with metamodeling-based design optimization methodology. The simulation results showed that tire snagging did not occur on the η-WG and the optimum design of the η-WG had an improved safety performance in vehicular crashes.

Mrutyunjay Rout and Amit Karmakar (Department of Mechanical Engineering, Jadavpur University, Kolkata, India), “Free vibration of rotating twisted composite stiffened plate”, Proceedings of the First International Conference on Mechanical Engineering, Jadavpur University, Kolkata, India, January 4-6, 2018, Paper No. INCOM18-039, 2018
ABSTRACT: The paper presents a finite element model based on first-order shear deformation theory to investigate the free vibration response of the rotating twisted composite stiffened plate. An eight nodded isoparametric plate element having five degrees of freedom per node is combined with a three node disoparametric beam element of four degrees of freedom per node for modelling the plate and the stiffener element, respectively. The formulation adopted here employs constraint technique to calculate stiffness and mass matrices of the stiffener element placed inside the plate element, wherein the nodal degrees of freedom of the stiffener element are transferred to the plate element considering curvature and eccentricity to maintain the compatibility between plate and stiffener. The advantage of such method is that there is no further increase in the total number of degrees of freedom due to addition of the stiffener, thereby reducing the computational time.

ABSTRACT: Combined isogeometric analysis (IGA) and shape optimization, this paper provides a method that can accurately analyze Tailor Rolled Blanks (TRB) and optimize its thickness profile continuously. While existed traditional methods can hardly solve these problems. TRB has a continuous transition between the thick and thin and a better surface quality. We found in IGA, two-dimension NURBS could present TRB geometry model exactly, but Kirchhoff shell element whose control points are allocated different thicknesses could not simulate TRB effectively. So, this paper uses three-dimension NURBS element to exactly present and accurately analyze TRB. It could avoid error caused by inaccurate presentation of geometry model and decrease error caused by solution field (displacement) approximation in numerical computation. Meanwhile, the positions of control points are taken as design variables in process of optimizing thickness profile. It can avoid the appearance of “unrealistic” shape and save lots of time spent in traditional tediously mesh updating as well as having better accuracy. This method makes accurate analysis and continuous thickness optimization of TRB become possible. It pushes the development of TRB engineering and extends the applications of IGA optimization. Several examples including benchmarks and application used the proposed method verified its effectiveness, reliability and efficiency.

As physical entities, living cells possess structural and physical properties that enable them to withstand the physiological environment as well as mechanical stimuli occurring within and outside the body. Any deviation from these properties will not only undermine the physical integrity of the cells, but also their biological functions. As such, a quantitative study in single cell mechanics needs to be conducted. In this review, we will examine some mechanical models that have been developed to characterize mechanical responses of living cells when subjected to both transient and dynamic loads. The mechanical models include the cortical shell–liquid core (or liquid drop) models which are widely applied to suspended cells; the solid model which is generally used for adherent cells; the power-law structural damping model which is more suited for studying the dynamic behavior of adherent cells; and finally, the biphasic model which has been widely used to study musculoskeletal cell mechanics. Based upon these models, future attempts can be made to develop even more detailed and accurate mechanical models of living cells once these three factors are adequately addressed: structural heterogeneity, appropriate constitutive relations for each of the distinct subcellular regions and components, and active forces acting within the cell. More realistic mechanical models of living cells can...

Graphdiyne possesses not only high strength but also excellent ductility, making it possible to be used in future high-performance protective structures. In this paper, the mechanical properties of graphdiyne were firstly measured by AFM experiments, and the failure behavior during low velocity perforation was also investigated by molecular dynamics (MD) simulations. Firstly, the elastic modulus was measured to be about 218.5 GPa by AFM experiments, which is about half of its ideal value due to various defects and the layer
numbers of the synthesized graphdiyne film. Then, the nanoindentation processes of graphdiyne films were investigated by MD simulations, and the elastic modulus and strength were simulated to be about 489.04 GPa and 33.95 GPa, respectively. The failure behavior of the graphdiyne film was also studied in atomic level. Sequential broken of C=C, C≡C and CeC bonds and recombination of the broken bonds were observed to form a unique latchy crack. Furthermore, the effects of loading speed and indenter radius on the mechanical response of graphdiyne were investigated. A revised formula was developed for analyzing the mechanical properties of films in AFM experiments under various loading conditions.

ABSTRACT: Nanoporous material functionalized liquid (NMFL) is now one of the candidates of advanced energy mitigation material, as supported by recent studies. In this study, quasi-static compression experiments and finite element (FE) simulations are conducted to investigate the energy absorption enhancement effect of NMFL as a filler in a thin-walled stainless steel tube. The influence of infiltration pressure (P_in), and the interaction effect between NMFL filler and tube wall are comprehensively explored. Results show that the filling with NMFL can enhance the energy absorption capacity of thin-walled tubes under axial compression by 25% at the present configuration, which comes from the nano-scale infiltration of NMFL by converting mechanical energy into excessive interfacial energy, and its interaction effect with thin-walled buckling. P_in has a significant impact on the energy absorption characteristics and buckling behavior.

ABSTRACT: The dynamic impact response of giant buckyball C720 is investigated by using molecular dynamics simulations. The non-recoverable deformation of C720 makes it an ideal candidate for high-performance energy absorption. Firstly, mechanical behaviors under dynamic impact and low-speed crushing are simulated and modeled, which clarifies the buckling-related energy absorption mechanism. One-dimensional C720 arrays (both vertical and horizontal alignments) are studied at various impact speeds, which show that the energy absorption ability is dominated by the impact energy per buckyball and less sensitive to the number and arrangement direction of buckyballs. Three-dimensional stacking of buckyballs in simple cubic, body-centered cubic, hexagonal, and face-centered cubic forms are investigated. Stacking form with higher occupation density yields higher energy absorption. The present study may shed lights on employing C720 assembly as an advanced energy absorption system against low-speed impacts.

ABSTRACT: In this paper three dimensional free vibration and transient response of a cylindrical panel made of two directionally functionally graded materials (2D-FGMs) based on three dimensional equations of elasticity.
and subjected to internal impact loading is considered. Material properties vary through both radial and axial directions continuously. The 3D graded finite element method (GFEM) based on Rayleigh-Ritz energy formulation and Newmark direct integration method has been applied to solve the equations in space and time domains. The fundamental normalized natural frequency, time history of displacements and stresses in three directions and velocity of radial stress wave propagation for various values of span angle of cylindrical panel and different power law exponents have been investigated. The present results show that using 2D-FGMs leads to a more flexible design than conventional 1D-FGMs. The GFEM solution have been compared with the results of an FG thick hollow cylinder and an FG curved panel, where a good agreement between them is observed.

ABSTRACT: We consider a host of regular lattice architectures and present analytical and computational approaches to derive the structure-property relationship for such structured material by exploiting the translational periodicity of infinite lattices. Two specific geometries – the so-called hexagonal honeycomb and the woodpile lattice – are studied analytically and computationally. The elasto-plastic response in the case of the first, and the bending response of lattice beams for the second, is considered. These specific problems have been motivated by biostructures relevant to medical implants and scaffolds. We also present novel methods to additively manufacture such lattices. When possible, the response is obtained as an analytical function of the microstructural parameters described by the geometry of the repetitive elements of the lattice, such as characteristic diameter, length, or thickness. Alternative methods of manufacturing materials with random internal architectures are also presented. The relative strengths and weaknesses of the two classes of materials with respect to analysis and manufacture are discussed.

ABSTRACT: On the basis of the Bloch’s theorem, the in-plane wave propagation in hexagonal and re-entrant lattice structures with cell walls of non-uniform thickness is investigated using the dynamic stiffness matrix in conjunction with the Wittrick–Williams algorithm. Special attention is devoted to the effects of the internal angle, the slenderness ratio and the material distribution on the directional and band gap behaviors. Results
show that the three considered parameters can significantly influence the band gap characteristics. For the wave propagation directionality, however, the internal angle is more prominent than the other two factors. The work expects to serve as a guide for the optimal design of directional mechanical filters.

ABSTRACT: Purpose – The purpose of this paper is to provide an efficient numerical solution for dynamic properties of sandwich tubes with honeycomb cores and investigate the effects of material distribution and relative density on the dynamic properties of the structure.

Design/methodology/approach – By introducing dual variables and applying the variational principle, the canonical equations of Hamiltonian system are constructed. The precise integration algorithm and extended Wittrick-Williams algorithm are adopted to solve the equations and obtain the dispersion relations of sandwich tubes. The effects of the material distribution and the relative density on the non-dimensional frequencies of the sandwich tubes are investigated. Findings – The validity of the procedure and programs is verified by comparing with other works. Dispersion relations of the typical sandwich tubes are obtained. Dramatic differences are observed as the material distribution and relative density of the sandwich structures vary. Originality/value – The work gains insight into the role of symplectic analysis in the structural dynamic properties and expects to provide new opportunities for the optimal design of sandwich tubes with honeycomb cores in engineering applications.

ABSTRACT: Topological-reinforcement and material-strengthening were used and employed to improve the mechanical properties of lattice truss sandwich structures. This new type of three-dimensional aluminum alloy lattice truss (named enhanced lattice truss) sandwich structure, with a relative density ranging from 1.7% to 4.7%, was designed and fabricated by interlocking and vacuum-brazing method. The out-of-plane compression and shear properties of the enhanced lattice truss sandwich structures (both as-brazed and age-hardened cores) were experimentally and analytically investigated. Good correlations between analytical predictions and experiment results were achieved. Experimental results showed that the mechanical properties of the enhanced lattice truss cores were sensitive to the unit-cell size and parent-alloy properties (i.e. inelastic buckling and tangential modulus). The compressive and shear characteristics of enhanced lattice truss sandwich structures were discussed and found superior to competing lattice truss structures in low density area (0.046-0.124 g/cm³) of material property charts. The combination of topological-reinforcement and material-strengthening provided a way to achieve lightweight sandwich structures with high specific strengths and low densities.

“Poisson-like effect for flexural waves in periodically perforated thin plates”, Journal of the Acoustical Society of America, Vol. 144, No. 2, August 2018

ABSTRACT: The Poisson-like effect, describing the redirection of waves by 90 degrees, is shown to be feasible for flexural waves propagating in perforated thin plates. It is demonstrated that the lowest order symmetric leaky guided mode (S0 mode) is responsible for the splitting of wave motion in two orthogonal directions. The S0 mode shows a feature of stationary waves containing standing wave modes in one and two orthogonal directions for smaller and larger holes, respectively. The former case is well understood thanks to the phenomenon of Wood’s anomaly, which was first observed in optical gratings supposed to be transparent. On the contrary, the strong scattering caused by the larger holes leads to a mixed mode occurring when the incident wave is totally transmitted. The mixed mode easily couples with the incoming waves and, therefore, the Poisson-like effect activated under this mechanism is much stronger. Using the Poisson-like effect, a device is proposed in which about 82% of the incident mechanical energy is redirected to the perpendicular direction. Results obtained with arrays of free holes also apply to inclusions with parameters properly chosen. The findings may provide applications in beam splitting and waveguiding.

ABSTRACT: We report on crease morphology and evolution at the surface of contracting cavities embedded within elastomeric solids of varying composition (Sylgard 184: pre-polymer to crosslinker mixing ratios of 10 : 1, 12 : 1, 17.5 : 1, and 25 : 1). Cavity contraction is achieved through evaporation of an embedded 10 mL liquid droplet. In validation of recent theoretical predictions, strain-stiffening modeled via the Gent constitutive relation [Jin and Suo, JMPS, 2015, 74, 68–79] is found to govern both crease onset and crease density. Specifically, crease matches prediction using only experimentally-measured parameters. Neo-Hookean solids are found to prefer initiating creasing with many short creases that join to form a collapsed state with only a few creases, whereas creasing in Gent solids initiates with a few creases that propagate across the cavity surface. These experimental observations are explained by energy minimization using finite element simulation of a cylindrical crease geometry.

“On the Identification of Sectional Deformation Modes of Thin-Walled Structures with Doubly Symmetric Cross-Sections Based on the Shell-Like Deformation”, Symmetry, Vol. 10, pp 759–, 2018
symmetric thin-walled cross-section, which are to be employed in formulating a one-dimensional model of thin-walled structures. The approach considers the three-dimensional displacement field of the structure as the linear superposition of a set of sectional deformation modes. To retrieve these modes, the modal analysis of a thin-walled structure is carried out based on shell/plate theory, with the shell-like deformation shapes extracted. The components of classical modes are removed from these shapes based on a novel criterion, with residual deformation shapes left. By introducing benchmark points, these shapes are further classified into several deformation patterns, and within each pattern, higher-order deformation modes are derived by removing the components of identified ones. Considering the doubly symmetric cross-section, these modes are approximated with shape functions applying the interpolation method. The identified modes are finally used to deduce the components of identified ones. Consecutive deformation patterns, and within each pattern, higher-order deformation shapes left. By introducing benchmark points, these shapes are further classified into several deformation patterns, and within each pattern, higher-order deformation modes are derived by removing the components of identified ones. Considering the doubly symmetric cross-section, these modes are approximated with shape functions applying the interpolation method. The identified modes are finally used to deduce the governing equations of the thin-walled structure, applying Hamilton’s principle. Numerical examples are also presented to validate the accuracy and efficiency of the new model in reproducing three-dimensional behaviors of thin-walled structures.

Course Title: Applications, advantages and challenge of composites. Plan of the course AE/ME/EMech 484 (11 pages) “Chapter 7: Sandwich Structures” (Table of Contents):
Introduction to sandwich structures
Governing equations
Boundary conditions for a sandwich plate
Static analysis of sandwich plates of composite materials
Applicability of the first order shear deformation theory (FSDT)
Experiments on sandwich panels: verification of theoretical models
Buckling of sandwich plates
Sandwich or laminated plates subjected to dynamic loads
Free vibrations of sandwich plates
Response of a sandwich plate subjected to a dynamic lateral load
Local buckling of sandwich panels
Buckling of Honeycomb Core Sandwich Panels Subjected to In-Plane Compressive Loads – Design Formulae
Cylindrical Sandwich Shells Under Axially Symmetric Loads – Design Formulae
Joints in sandwich structures
Fatigue properties of sandwich core materials

ABSTRACT: Sandwich panels have the best stiffness-to-lightness ratio, which is what makes them very useful in industrial applications. This paper is focused on a study of the buckling capacities of the core components under uniaxial compression. The critical buckling loads for various core densities and materials of honeycomb panels were experimentally and numerically investigated. The specimens under lateral loading showed three zones: zone 1 is the initial elastic state, followed by the plateau region in zone 2, while zone 3 shows a monotonically stiffening region, associated with the densification of the material. The effect of the core density and its materials on the behavior and the damage was highlighted. From the experiment it is clear that the buckling load of the specimens increases as the core density is increasing. In terms of stiffness and load at failure, the honeycomb sandwich panel had better mechanical characteristics than its components. The study also calculated the numerical buckling loads of the panels using the ABAQUS finite-element analysis program. The achieved experimental and numerical results were compared with each other. In conclusion, a good correlation between theory and experiment was found.

ABSTRACT/INTRODUCTION: Sandwich structures, made with two skins characterized from high mechanical performances and a core with lower mechanical properties, are widely used in different fields of engineering, mostly in aeronautic and aerospace industries. The success of sandwiches structures is mainly due to the possibility of optimising the structural response by an opportune choice of materials and geometry. In particular, the introduction of composite laminates, as skins materials, allows attaining an optimal solution in terms of mechanical response, weight and costs. More generally the tailor ability of the structures, on the basis of the specific application, makes such elements very attractive; in fact faces can be designed varying the geometry, the fibers orientation, the kind of materials by means the hybridisation technique. On the other hand the core materials can be varied in geometry and mechanical properties, from a more traditional rigid core material to a soft one.

The high performances of sandwich structures, in particular sandwich panels, allow a reduction of geometrical dimension, mostly as regard the thickness, obtaining very often a structure with high slenderness. For this reasons the predominant mechanisms of failure are those related to instability instead to the attainment of the ultimate strength. Different kinds of instability may take place, depending on sandwich panel properties, as global buckling, local buckling or even an interaction between local and global instability.

Several studies have been made on this topic and results are available in the literature [1], [2], [3], [4], [5], [6]. Stability problems become more critical in presence of imperfections, such delaminations. Delaminations can be caused both from mechanical or environmental conditions and can involve the laminas interface or the skin-core interface. The prediction of buckling load of delaminated plates and sandwiches have been studied from many researchers by utilizing both analytical and numerical approaches [7], [8], [9], [10], [11].

In the present paper a numerical, FEA, approach is presented to determine the initial buckling load of delaminated sandwich plates under compression, with the delamination zone interesting the skin-core interface. The utilized numerical model uses three dimensional brick elements for every constituent part taking into account the whole state of strain and stress; the analysed delamination zone is centred within the panel, rectangular in shape, and having dimensions D and H. Buckling loads and buckled panels configurations are evaluated varying the damage degree, that is the delaminated zone dimensions. Different kinds of skins and core are analysed and the buckling phenomenon, referring to initial buckling load and buckling configuration, is investigated varying some key parameters, as the panel aspect ratio, the mechanical properties of core and skins, the thickness of the skins and the core, the boundary conditions. A mesh sensitivity analysis has been also performed preventively.

ABSTRACT: Sandwich structures are efficient lightweight materials. Due to their design they exhibit very special failure modes such as global buckling, shear crimping, face-sheet wrinkling, face-sheet dimpling, and face/core yielding. The core of the sandwich is usually made of foams or cellular materials, e.g., honeycombs. Especially in the case of honeycomb cores the correlation between analytical buckling predictions and experiments might be poor (Ley, Lin, and Uy (1999)). The reason for this lies in the fact that analytical formulae typically assume a homogeneous core (continuous support of the facesheets). This work highlights problems of honeycomb core sandwiches in a parameter regime, where the transition between continuous and discrete support of the facesheets is studied. Periodic finite element unit cell models are utilized for this task, which offer the big advantage of a homogeneous load introduction to the structure. The finite element models are found to be well suited for all kinds of buckling predictions. Different uni- and bi-axial loadings are considered as well as influences of core height, core material, core geometry, and facesheet thickness are investigated. Finally, a new analytical approach is introduced for the unexpected core wall buckling under in-plane compression of the sandwich, which predicts the critical load very accurately.

ABSTRACT: A three-layer quasi 3D finite element model for buckling analysis of sandwich plates with laminated composite face-sheets is evaluated. In the model, the face-sheets are represented as Reissner-Mindlin plates and the core is modeled as a three-dimensional continuum. This representation allows accurate modeling for a wide range of core types. The three-dimensional problem is reduced to two dimensions by analytical through-thickness integration of the energy expressions for the evaluation of stiffness matrices. The stress stiffening effect is included in the quasi 3D model through the formulation of appropriate geometric stiffness matrices. Linearized buckling analyses of sandwich plates are performed. The purpose is to compute critical
loads and respective buckling modes from the solution of the eigenvalue problem by the subspace iteration method. A membrane state of stress can be easily established when applying the Reissner-Mindlin theory to the face-sheets. However, the quasi 3D formulation considers that the core behaves like a 3D structure connected to the face-sheets. This situation indicates the use of a general formulation that takes into account not only the membrane strains, but also all strain components to yield the geometric stiffness matrix.

Buckling problems are studied in order to validate the implemented code and demonstrate that linearized buckling loads of a sandwich plate may be strongly influenced by the variation of the core stiffness. The problem of buckling of sandwich plates with core discontinuity is also addressed.

ABSTRACT: The transverse compression and shear collapse mechanisms of a second order, hierarchical corrugated truss structure have been analyzed. The two competing collapse modes of a first order corrugated truss are elastic buckling or plastic yielding of the truss members. In second order trusses, elastic buckling and yielding of the larger and smaller struts, shear buckling of the larger struts, and wrinkling of the face sheets of the larger struts have been identified as the six competing modes of failure. Analytical expressions for the compressive and shear collapse strengths in each of these modes are derived and used to construct collapse mechanism maps for second order trusses. The maps are useful for selecting the geometries of second order trusses that maximize the collapse strength for a given mass. The optimization reveals that second order trusses made from structural alloys have significantly higher compressive and shear collapse strengths than their equivalent mass first order counterparts for relative densities less than about 5%. A simple sheet metal folding and dip brazing method of fabrication has been used to manufacture a prototype second order truss with a relative density of about 2%. The experimental investigation confirmed the analytical strength predictions of the
second order truss, and demonstrate that its strength is about ten times greater than that of a first order truss of the same relative density. DOI: 10.1115/1.2198243

ABSTRACT Fiber-reinforced plastic corrugated core sandwich panels were tested for buckling in uniaxial compression. Three types of corrugation i.e. sinusoidal, square and triangle of different thickness core of epoxy based were tested. The sandwich panels were fabricated using the hand layup method process. The two short edges of the sandwich panels were clamped, while the two long edges were simply supported for testing. A Bifurcation in the load versus engineering strain curve was noted in all cases. For all sandwich panels tested using corrugation core, the type of failure was easily identified as face sheet delamination followed by core shear failure. In the failed core panels there was little or no evidence of core remaining on the FRP face sheet, however, lower strain rate in the PVC foam core panels there were ample amounts of foam left on the FRP face sheet. It was concluded that although the buckling loads for the sinusoidal corrugated core panels showed very high buckling strength.

ABSTRACT: This paper deals with the buckling response and nonlinear behavior of sandwich panels with soft cores that have temperature-dependent mechanical properties and are subjected to thermally induced deformations and mechanical loads simultaneously. This study investigates the effects of the degradation of properties of the core as a result of rising temperature on the response of the sandwich panel. Analyses are carried out for cases of pure thermal loading, with either uniform or gradient temperature fields through the depth of the panel, as well as for thermal loading acting simultaneously with external mechanical loads. The formulation is based on variational principles along with the high-order sandwich panel approach. It takes into account the flexibility of the core in the vertical direction as well as the dependency of the mechanical core properties of the temperature distribution through the core depth. The stress and deformation fields of the core have been solved analytically, including the case where the temperature-dependent properties attain a complex pattern. The buckling equations are derived using the perturbation technique, yielding a set of nonlinear algebraic equations for the case of a simply-supported panel and a uniform temperature field. The critical temperatures and modes of wrinkling and global buckling are determined numerically for some foam types of core made by Rohacell and Divinycell. The nonlinear response caused by thermally induced deformations is presented for Divinycell foam core with different temperature distributions through the depth of the core. Finally, the nonlinear response caused by the simultaneous action of external mechanical loading and increased temperatures on the compressive or the tensile side of the panel, with a thermal gradient through the core depth, is presented. The interaction between elevated temperatures and mechanical loads changes the response from a linear into an unstable nonlinear one when the degradation of the mechanical properties due to temperature changes is considered and the panel is unrestrained. Moreover, the unstable nonlinear behavior becomes even more severe when the face, loaded in compression, is subjected to elevated temperatures. This study reveals that a reliable, realistic design of a sandwich panel that is subjected to elevated temperature (within working temperature range) and mechanical loads must take into account the degradation of the properties of the core as a result of the thermal field even at working temperature range, especially when cores made of foam are considered.

ABSTRACT: Past research into the local buckling behaviour of fully profiled sandwich panels has been based on polyurethane foams and thicker lower grade steels. The Australian sandwich panels use polystyrene foam and thinner and high strength steels, which are bonded together using separate adhesives. Therefore a research project on Australian sandwich panels was undertaken using experimental and finite element analyses. The experimental study on 50 foam-supported steel plate elements and associated finite element analyses produced a large database for sandwich panels subject to local buckling effects, but revealed the inadequacy of conventional effective width formulae for panels with slender plates. It confirmed that these design rules could not be extended to slender plates in their present form. In this research, experimental and numerical results were used to improve the design rules. This paper presents the details of experimental and finite element analyses, their results and the improved design rules.

ABSTRACT: Despite of laminate or sandwich composite materials structure, mechanical behavior can estimate by methods or analytical relations like laminates classical theory according factors just like mechanical properties, fiber percentage, and product methods and etc. but generally these estimates are far from experimental results. This paper investigates about influence of product methods and different cores on buckling and post buckling behaviors of sandwich panels. Each panel was built by to quit different product method, hand layup or vacuum bag infusion procedure with different core. To build the panels an effort had made to choice materials which have usage in marine industry, special for high speed boats. Sandwich panels have 150x450 mm² dimensions and one simply support and one clamed support. After tests, numerical models results which drive from finite element software are compared with experimental data. The results represent that combined model is suitable for simulate buckling and post buckling behavior. After chosen the software model, different parameters were evaluated whom the link element has the most efficacy on numerical results.

Khaina Sad Saoud and Phillippe Le GrogneC (Mines Douai, Polymers and Composites Technology & Mechanical Engineering Department, Douai, France), “Buckling and post-buckling analysis of sandwich beam-columns”, 11th World Congress on Computational Mechanics (WCCM XI), 5th European Conference on
ABSTRACT/INTRODUCTION: Sandwich structures are increasingly used in many industrial applications, due to the attractive combination of a lightweight and strong mechanical properties. This compromise is realized thanks to the presence of different parts in the composite material, namely the skins and possibly core reinforcements or thin-walled core structure which are both thin/slender and stiff relative to the other parts, namely the homogeneous core material, if any. The buckling phenomenon thus becomes mainly responsible for the final collapse of such sandwiches. One usually distinguishes two types of geometric instabilities, namely the global buckling of the sandwich structure under overall compression and the so-called wrinkling (or local buckling) of the faces which may appear under various loadings. Global buckling can easily be viewed as the classical buckling of the equivalent homogenized structure and only involves the effective properties of the heterogeneous beam or plate in hand. Conversely, the wrinkling analysis requires the use of advanced models. This study first deals with the linearized buckling/wrinkling response of classical sandwich beam-columns (with homogeneous core materials). Based on a 3D elastic bifurcation analysis, closed-form analytical solutions of the critical loadings and the associated bifurcation modes are derived in a unified way for both mode types (global and local) and with various loading conditions [1]. The present analytical solutions are in much better agreement with reference numerical results, in comparison with previous analytical solutions from the literature, thanks to the particular choice of the kinematic hypotheses in the skins (modeled by Euler-Bernoulli beams) and the core layer (considered as a 2D continuous solid).

Then, the advanced post-buckling response of sandwich columns under axial compression is investigated. For this purpose, a specific home-made 2D finite element code is used. It includes (i) branch-switching procedures, that allow one to detect the true bifurcation points (without introducing any imperfection) and bifurcate onto a given branch, and (ii) arc-length methods, which enable one to deal with possible strong non-linearities (non-monotonous curves). The post-critical response of such structures is shown to be always stable after the primary (global or local) bifurcation mode. However, a secondary mode often occurs in practice and leads to an unstable post-buckling behavior, very sensitive to imperfections, as shown in Leotoing et al. [2]. The secondary bifurcation mode proves to be local when the primary mode is global and vice versa (see Figure 1 for an example of the successive deformed shapes during the post-buckling stage). Such a non-linear response is particularly observed when the first two (global and local) primary critical loads are close to each other, and it is referred to as the modal interaction phenomenon.

Finally, for efficiency purposes, an enriched beam finite element model is proposed, as an alternative to our robust but time-consuming 2D model. The main idea is to define the beam kinematics from the exact analytical mode shape of each layer, in order to capture local effects (such as the wrinkling of the faces) during the buckling and post-buckling analyses, following the example of Hu et al. [3].

ABSTRACT: Four honeycomb sandwich panels, representing 1/16th arc segments of a 10 m diameter barrel section of the heavy lift launch vehicle, were manufactured under the NASA Composites for Exploration program and the NASA Constellation Ares V program. Two configurations were chosen for the panels: 6-ply facesheets with 1.125 in. honeycomb core and 8-ply facesheets with 1.000 in. honeycomb core. Additionally, two separate carbon fiber/epoxy material systems were chosen for the facesheets: in-autoclave IM7/977-3 and out-of-autoclave T40-800B/5320-1. Smaller 3- by 5-ft panels were cut from the 1/16th barrel sections. These
panels were tested under compressive loading at the NASA Langley Research Center. Furthermore, linear eigenvalue and geometrically nonlinear finite element analyses were performed to predict the compressive response of the 3- by 5-ft panels. This manuscript summarizes the experimental and analytical modeling efforts pertaining to the panel composed of 8-ply, T40-800B/5320-1 facesheets (referred to as Panel C). To improve the robustness of the geometrically nonlinear finite element model, measured surface imperfections were included in the geometry of the model. Both the linear and nonlinear, two-dimensional (2-D) and three-dimensional (3-D), models yield good qualitative and quantitative predictions. Additionally, it was predicted correctly that the panel would fail in buckling prior to failing in strength.

ABSTRACT: Sandwich columns, comprising woven glass reinforced epoxy face sheets and PVC polymer foam core, have been tested under edgewise compressive loading. Failure is by Euler macrobuckling, shear macrobuckling or by face sheet microbuckling, depending upon the material combination and geometry of column. Simple analytical models are developed for the axial strength, and these are in good agreement with the experimental values for each failure mode. Collapse mechanism maps are constructed to illustrate the dependence of failure mode upon the geometry and relative density of the core; and minimum weight designs are determined as a function of the appropriate structural load index.

ABSTRACT: The paper deals with the theoretical prediction of buckling loads for sandwich columns with metallic and laminated facings and foam or honeycomb core. The loading is a uniform axial compression, applied statically (very slowly) and suddenly with constant magnitude and infinite duration (step loading). The effect of length and boundary conditions is assessed and results are presented for the following cases: for a cantilever column, a simply supported column and a clamped column, for several lengths. Several fiber materials are used in the laminated facings. Two types of core were examined: alloy-foam or hexagonal glass-phenolic honeycomb. The facings are Boron-Epoxy, Graphite-Epoxy and Kevlar-Epoxy laminates with 0 degree orientation with respect to the column axis and a metallic one made out of aluminum. These various materials are employed to provide comparative data that can be used in design. Results, for the static case are generated by computer codes as well as by the use of closed form theoretical solutions. For the dynamic case, results are generated by the DYNA3D code.

ABSTRACT: In this paper, the behavior of free vibrations and buckling of the sandwich panel with a flexible core was investigated using a new improved high-order sandwich panel theory. In this theory, equations of motion were formulated based on shear stresses in the core. First-order shear deformation theory was applied for the procedures. In this theory, for the first time, incompatibility problem of velocity and acceleration field existing in Frostig’s first theory was solved using a simple analytical method. The main advantage of this theory is its simplicity and less number of equations than the second method of Frostig's high-order theory. To extract dynamic equations of the core, three-dimensional elasticity theory was utilized. Also, to extract the dynamic equations governing the whole system, Hamilton's principle was used. In the analysis of free vibrations, the panel underwent primary pressure plate forces. Results demonstrated that, as plate pre-loads got closer to the critical buckling loads, the natural frequency of the panel tended zero. The results obtained from the present theory were in good correspondence with the results of the most recent papers.

ABSTRACT: The low velocity impact response of a range of foam based sandwich structures has been investigated using an instrumented falling weight impact tower. Initially, the rate-sensitivity of the skin and core materials was investigated through a series of flexure and indentation tests. It was shown that the flexural modulus of the skins and all 11 foam materials did not exhibit any sensitivity to crosshead displacement rate over the conditions studied here. In addition, it was shown that the indentation response of the sandwich structures could be modelled using a simple indentation law, the parameters of which did not exhibit any sensitivity to loading rate. Low velocity impact tests on the sandwich structures resulted in a number of different failure modes. Shear fracture was found to occur in the PVC/PUR systems based on brittle core materials. In contrast, buckling failures in the uppermost composite skin were observed in the intermediate modulus systems, whereas initial damage in the higher modulus PVC/PUR systems took the form of delamination within the top surface skin. It has been shown that a simple energy balance model based on the dissipation of energy during the impact event can be used to successfully model the elastic response of foam based sandwich structures. The energy balance model is particularly useful since it can be used to establish the partition of energy during the impact process.

ABSTRACT: An analytical pilot model for interactive buckling in sandwich struts with cores made from a functionally graded material based on total potential energy principles is presented. Using a Timoshenko beam approach, a system of nonlinear differential and integral equations is derived that predicts critical and secondary instabilities. These are validated against numerical simulations performed within the commercial finite-element package Abaqus. Good agreement is found, and this offers encouragement for more elaborate models to be devised that can account for face-core delamination—a feature where functionally graded materials are known to offer distinct advantages.

ABSTRACT: In present work, the critical buckling load of metallic foam composite sandwich panels is calculated by experimental, finite element methods (FEM) and theoretical analysis. The experimentally investigated is based on an edgewise compression test program to examine buckling failure and compressive properties. The metallic foam sandwich panels under edgewise compression tend to collapse in overall buckling mode. The most important factor that determines the overall buckling load of a sandwich panel under edgewise compression is the shear properties the metallic foam core. The sandwich beam theory and the FE model are developed for prediction of the buckling load of metallic foam sandwich structure. In despite of some differences existed among experimental data, FE and theoretical results, considering the existence of initial defects in sandwich structures which can’t be calculated in FE model and theory analysis, the differences are in the reasonable range. The FE program developed in this paper can effectively be used to simulation of edgewise compression response for metallic foam composite sandwich structures. Theoretical and FE model results are in agreement with experimental result.

ABSTRACT: An unbalanced and asymmetric sandwich composite structure consisting of Titanium 6-4 and glass-reinforced plastic (GRP) skins with a phenolic honeycomb core is being considered for construction of a surface ship mast which will enclose critical shipboard equipment. Stability of the structure is one of the major concerns in the design process. This research focuses on analytical and experimental studies of an unbalanced
composite sandwich beam subjected to a compressive axial load. The failure load (i.e., peak load) and failure mode of each skin material and the sandwich construction were measured at the laboratory. An analytical model was developed for predicting the failure load of the unbalanced and asymmetric sandwich composite configuration, including the transverse shear energy of the core material. The experimental data agreed very well with analytical prediction. Postbuckling failure, as well as residual strength after initial failure, were also studied.

ABSTRACT: A sandwich structure typically consists of two facesheets separated by lightweight core. Buckling is one of the critical failure modes for sandwich structure in particular for relatively large panels. A sandwich can be treated as a laminate where the core is just another ply with negligible stiffness and strength properties and thickness equal to the core thickness. Buckling is one of the critical failure modes for sandwich structure in particular for relatively large panels. The reason is that it is hard to design against all possible failure modes in the post-buckling regime and, as a result, buckling is usually considered to coincide with final failure. Wrinkling is a local buckling phenomenon where the facesheet of a sandwich buckles over a characteristic half-wavelength \( l \), which is unrelated to the overall length or width of the panel. This chapter also discusses sandwich intracellular buckling under compression and attaching sandwich structures.

ABSTRACT: A formula is derived for the buckling in compression of an orthotropic sandwich panel, with all edges simply-supported. Two special types of symmetrical sandwiches, that of a sandwich having zero core flexural stiffnesses and of a corrugated core sandwich, are considered, and curves giving the critical buckling end load per inch are presented. An approximate theory is also given for the bending of sandwich panels under the action of an axial compressive load and a uniform lateral pressure. Curves are presented giving the maximum bending moments in a corrugated core sandwich panel.

ABSTRACT: (Cannot cut and paste it.)

ABSTRACT: A sandwich structure is comprised of layered composite materials formed by bonding two or more thin facings or facesheets to a relatively thick core material. This article describes the sandwich panel failure modes. It tabulates the nomenclature and definitions for loads, geometry, and material properties. The article illustrates critical strength-check locations for a flat sandwich panel. It discusses the analysis methods formulated for flat rectangular honeycomb panels; curved sandwich panel; and for each of the various sandwich panel failure modes. The article concludes with a discussion on flat panel stability analysis methods.

ABSTRACT: A recent six degree-of-freedom interactive buckling analysis for sandwich struts is extended from isotropic to orthotropic core materials. The interaction, which involves an overall mode of buckling coupled with local wrinkling predominantly on one face, arises as a progressive destabilization from neutral bifurcation in the overall mode alone to a highly unstable secondary bifurcation in a combination of three independent buckling modes. The analytical model, which allows separately for bending and shear deformations in the core, is illustrated by application to a set of typical sandwich struts. An optimum core orthotropy that maximizes the interaction is found. In combination with the earlier optimum wavelength for local wrinkling, this suggests that secondary destabilization can occur almost immediately after the initial (triggering) bifurcation.

ABSTRACT: Compressed sandwich structures, comprising two stiff face plates separated by a softer core material, while designed principally as efficient integral structures, can lose this quality when faces buckle locally. Interaction between overall (Euler) buckling and local buckling of one face suggests that failure will localize into the centre. A variational formulation, leading to a pair of nonlinear differential equations subject to integral constraints, describes the post-buckling response. These are solved by a combination of numerical shooting and continuation techniques, such that the response far into the unstable post-buckling regime can be portrayed. Solutions with both linear and nonlinear constitutive core relations are compared with the results of an engineering (body-force) approach, and with those of earlier (periodic) Rayleigh–Ritz analyses. The latter demonstrate the extra destabilization that comes with localization.

Koiter, W. T. & Pignataro, M. 1976 A general theory for the interaction between local and overall buckling of stiffened panels.
WTHD 83. Delft: Delft University of Technology.

ABSTRACT: Recent work on the interactive buckling behaviour of compressed sandwich structures (Hunt & Wadee, 1997) is extended to orthotropic core materials. The variation of the material properties can tend to maximize the interactive effect such that overall and secondary localized modes are triggered almost simultaneously, giving rise to highly unstable post-buckling behaviour in systems of practical dimensions.

References listed at the end of the paper:

ABSTRACT: A progressive destabilization in compressed elastic structures of sandwich construction is identified, whereby a triggering bifurcation into an overall mode of buckling is rapidly followed by secondary bifurcation into an unstable combination of at least two local modes. A six degree-of-freedom analysis for a sandwich strut is provided, which tracks equilibrium paths for a perfect system, specifically pinpointing states of secondary bifurcation. The analytical model allows for the independent variation of bending and shear in the section, components that are found in significantly different combinations in the overall and local forms of buckling that make up the interaction. An optimum wavelength for local buckling is identified, which maximizes the interactive effect by bringing the primary and secondary bifurcations together. Examples of sandwich sections drawn from the literature are tested. Although the critical loads of two of the contributing modes are often considerably higher than the third (typically by multiples of two or more), the preference for the broken symmetry of the interactive form is such that secondary bifurcation into the combination of modes is always to be expected.

Alexander E. Lobkovsky, “Structure of crumpled thin elastic membranes”, PhD thesis, Department of Physics, University of Chicago, Department of Physics, Chicago, August 1996
ABSTRACT: In this thesis we explore forced crumpling of a thin elastic membrane. As in many problems that involve bending of elastic plates and shells, the limit of the vanishing membrane thickness leads to a boundary layer phenomenon. We argue that the structure of a crumpled sheet in that limit is simple. It consists of a collection of flat facets that are bounded by straight edges that in turn meet at sharp vertices. These edges become infinitely sharp in the small thickness limit. A boundary layer solution in the ridge region determines the details of how the singular limit of a sharp crease is approached. Most of the elastic energy is confined into
the ridges. A scaling law allows one to estimate the energy of a ridge given only its length and dihedral angle. Thus, if for a given compression factor, a crumpled sheet can be characterized in terms of the underlying ridge network, one can estimate its elastic energy and therefore its resistance to further compression.

Kawai Kwok, “Mechanics of viscoelastic thin-walled structures”, PhD Dissertaint, California Institute of Technology, Pasadena, California, USA, 2013

ABSTRACT: Thin-walled structures made of polymers and reinforced polymer composites are prominent candidates for constructing large lightweight structures. A major challenge in designing polymer-based thin-walled structures is their time and temperature dependent behavior originating from material viscoelasticity and its interaction with the highly geometrically nonlinear response due to thinness of the walls. Although polymer viscoelasticity and geometric nonlinearity have been extensively studied, the mechanics of structures exhibiting both phenomena are not well understood.

This thesis presents a combination of experimental, numerical, and analytical investigations of the behavior of viscoelastic thin-walled structures. The first goal of this research is to establish general methods of analysis for two types of structural components, namely composite shells and polymer membranes, that will serve as the basis for full-scale structural analysis. The second goal is to demonstrate the capability of the developed methods by analyzing time and temperature dependent behavior of deployable structures and balloon structures. In the study of deployable structures, the deployment and shape recovery processes after stowage are investigated. Fundamental features of viscoelastic deployable structures are studied first with homogeneous polymer beams and shells. A simple closed-form solution describing the shape evolution of a beam after stowage is proposed. The effects of rate and temperature on the bending instability of shells are revealed.

Building on the understanding gained from the analysis of homogeneous structures, modeling techniques are developed for polymer composite structures. A micromechanical viscoelastic model for carbon fiber reinforced polymer thin shells is established through finite element homogenization and applied to evaluate the effects of long-term stowage in a representative composite deployable structure.

In the study of balloon structures, a membrane model is developed to study polymer balloon films with stress concentrations due to thickness variation. A nonlinear viscoelastic constitutive model is first formulated for the film material. The wrinkling instability behavior is incorporated into the model through correction of stress and strain states in the presence of wrinkling. Stress concentration factors in balloon films are predicted and measured with the membrane model and full-field displacement measurement techniques, respectively.

ABSTRACT:

ABSTRACT: As the engineering profession moves from prescriptive or “deemed-to-satisfy” approaches towards design methodologies based on quantification of performance, sophisticated modelling tools are increasingly needed, especially when complex combinations of demand and capacity are encountered. Recourse is invariably made to advanced computational tools to provide high fidelity solutions to large and complex problems, such as the response of structural systems or components to thermomechanical actions. Software packages based on the finite element method are most commonly used for such analyses. There are some essential prerequisites to effective use of advanced computational software for complex nonlinear problems, which are often ignored, particularly in professional practice. These include a thorough understanding of the underlying mechanics of the problem under consideration; a good appreciation of the approximation methods for modelling the problem properly (e.g. the choice between elements, continuum or structural, low or high order interpolation, degree of mesh refinement necessary and so on); and perhaps most importantly ensuring that the software is reliable and is able to reproduce established fundamental solutions to an acceptable degree of accuracy.

This thesis attempts to address most of these issues but focusses primarily on the last mentioned prerequisite and provides a range of novel and unprecedented fundamental solutions for beams, plates, and shallow shells subject to moderate or extreme thermomechanical loads such as those resulting from a fire. Geometric and material nonlinearities are included in the proposed formulations along with the most common idealised boundary conditions. Thermally induced deformations generate large displacements and require the solutions to account for geometric nonlinearity, while material nonlinearity arises from the degradation of the material at
elevated temperatures. In the context of structural performance under extreme thermal action (such as fire), a finite element procedure is employed to analytically characterise generic temperature distributions through the thickness of a structural component arising from different types of fire exposure conditions including: a “short hot” fire leading to a high compartment temperature over a relatively short duration; and a “long cool” fire with lower compartment temperatures, but over a longer duration.

Results have shown that despite the larger area under the long cool fire time-temperature curve, which traditionally represented the fire severity, the effect of the short hot fire on the nonlinear responses of beams, plates, and shallow shells is more pronounced. Also, the effect of temperature-dependent material properties is found to be more pronounced during the short hot fire rather than the long cool fire. Comparison studies have confirmed that while the current numerical and theoretical approaches for analysing of thin plates and shells are often computationally intensive, the proposed approach offers an adequate level of accuracy with a rapid convergence rate for such structures. The solutions developed can be used to: verify software used for modelling structural response to thermomechanical actions; help students and professionals appreciate the fundamental mechanics better; provide relatively quick solutions for component level analyses; and visualise internal load paths and stress trajectories in complex structural components such as composite shells that can help engineers develop deeper insights into the relevant mechanics. The formulations developed are versatile and can be used for other applications such as laminated composite or orthotropic shallow shells. A very significant by-product of developing such fundamental solutions is their potential use in the development of highly accurate hybrid elements for very efficient modelling of large problems. While this has not been fully developed and implemented in the current work, the requisite theoretical framework has been developed and reported in one of the appendices, which can be used to develop such elements and implement on an appropriate software platform.

Rasmussen (School of Civil Engineering, the University of Sydney, Sydney, NSW 2006, Australia), “Material and geometric nonlinear isoparametric spline finite strip analysis of perforated thin-walled steel structures - analytical developments”, Thin-Walled Struct., 49 (2011), pp. 1359–1373

ABSTRACT: This paper presents the analytical developments of the application of the Isoparametric Spline Finite Strip Method (ISFSM) to the material inelastic and geometric nonlinear analysis of perforated thin-walled steel structures. The general theory of the ISFSM is briefly introduced. The formulations of the kinematics, strain–displacement and constitutive assumptions are presented, and the tangential stiffness matrix is derived by applying the incremental equilibrium condition. The requirements for strip continuity and boundary conditions

are also discussed. In particular, the plasticity theory and the methods to integrate the ‘rate equations’ are
emphasized, and the related ‘backward Euler return method’ and use of a ‘consistent material modulus’ are
highlighted. The present isoparametric spline finite strip analysis is verified against a number of analyses of
perforated and non-perforated plates and plate assemblages, as described in the companion paper (Yao and
Rasmussen, submitted for publication) [1], demonstrating its accuracy and efficiency for the predictions of
the inelastic post-buckling behavior of perforated thin-walled steel structures.

ABSTRACT: This thesis is devoted to the numerical solution of dynamic problems involving thin-walled structures. Special consideration is paid to the effects of contact-impacts. Thus, the main effort is concentrated on studies, development and computer program implementations of efficient algorithms for analysis of dynamically loaded shell structures, including contact-impacts and severe structural deformation.

Recent developments in the formulation of efficient finite elements for dynamically loaded shell structures are studied. A program implementation of a low-order four-node shell element with uniformly reduced integration is performed. The efficiency and the behaviour of this element type are compared with existing shell and solid elements implemented in the same program system. Hourglass resisting algorithms are reviewed and formulated, and parameter studies are carried out.

A new contact interface algorithm for dynamic analysis with explicit integration is presented. The development of the defence node algorithm permits contact constraints based on the Lagrange multiplier method to be introduced in dynamic analysis with explicit integration. Numerical tests show the good performance of the developed algorithms.

A new global search method for general contacting systems is developed and implemented in a computer program together with the above-mentioned contact interface algorithm. The concept of position codes for efficient global contact searching and the local search procedure used are presented. Numerical experiments are performed in order to examine the behaviour of the algorithms in different aspects.

materials with engineered microstructures, such as polymer composites and nanotube. Though the well-established finite element analysis (FEA) has the ability to analyze a small portion of such material, for the whole structure, the total degrees of freedom of a finite element model can easily exceed the bearable time in analysis or the capability of the best mainstream computers. To reduce the total degrees of freedom and save the computational efforts, an efficient way is to use a simpler and coarser mesh at the structure level with the micro level complexities captured by a homogenization method. Throughout the dissertation, the homogenization is carried on by variational asymptotic method which has been developed recently as the Variational Asymptotic Method for Unit Cell Homogenization (VAMUCH). This methodology is also expandable to the structure analysis as long as a representative structural element (RSE) can be obtained from structure. In the present research, the following problems are handled: (1) Maximizing the flexibility of choosing a RSE; (2) Bounding the effective properties of a random RSE; (3) Obtaining the equivalent plate stiffnesses for a corrugated plate from a RSE; (4) Extending the shell element of relative degree of freedom to analyze thin-walled RSE. These problems covered some important topics in homogenization theory. Firstly, the rules need to be followed when choosing a unit cell from a structure that can be homogenized. Secondly, for a randomly packed structure, the efficient way to predict effective material properties is to predict their bounds. Then, the composite material homogenization and the structural homogenization can be unified from a mathematical point of view, thus the repeating structure can be always simplified by the homogenization method. Lastly, the efficiency of analyzing thin-walled structures has been enhanced by the new type of shell element. In this research, the first two topics have been solved numerically through the finite element method under the framework of VAMUCH. The third one has been solved both analytically and numerically, and in the last, a new type of element has been implemented in VAMUCH to adapt the characteristics of a thin-walled problem. Numerous examples have demonstrated VAMUCH application and accuracy as a general-purpose analysis tool.

Paul Gerrard Duxbury, “Solution of elasto-plastic plate and shell problems using the generalized Galerkin method”, PhD Dissertation, Civil Engineering Department, Imperial College of Science and Technology, January 1988

ABSTRACT: This thesis describes the means of nonlinear structural analysis by microcomputer, whereby the machine replaces the analytical flow produced classically by hand. The automation of the analysis allows the full evaluation of the performance of Galerkin's method for the competitive solution of a specialized class of plate and shell problems.

A comprehensive program to follow the proposed routines was written and applied to a selection of plate and shell problems, including both material and geometric nonlinearities.

In addition, different aspects of nonlinear mechanics are examined. Considering material nonlinearity, methods which eliminate ‘drift’ from the yield surface and accurately integrate stresses through a shell thickness are proposed. For an elastic system, various aspects of structural stability are discussed and a method to solve for nonlinear bifurcation paths developed.

ABSTRACT:
Mechanical Engineering, The University of British Columbia, Canada 1994

ABSTRACT: Peripheral milling of flexible components is a commonly used operation in the aerospace industry.
Aircraft wings, fuselage sections, jet engine compressors, turbine blades and a variety of mechanical components have flexible webs which must be finish machined using long slender end mills. Peripheral milling of very flexible plate structures made of titanium alloys is one of the most complex operations in the aerospace industry and it is investigated in this thesis.

Flexible plates and cutters deflect statically and dynamically due to periodically varying milling forces and self excited chatter vibrations. Static deflections of the plate and cutter cause dimensional form errors, whereas forced and chatter vibrations result in poor surface quality and chipping of the cutting edges. In this thesis, a comprehensive model of the peripheral milling of very flexible cantilever plates is presented. The plate and cutter structures are modeled by 8 node finite elements and an elastic beam, respectively. The cutting forces are shown to be very dependent on the magnitude of the plate and cutter deformations which are irregular along the helical end mill-plate contact. The interaction between the milling process and cutter-plate structures is modeled, and the milling forces, structural deformations and dimensional form errors left on the finish surface are accurately predicted by the simulation system developed in this study. A strategy, which constrains the maximum dimensional form errors caused by static deformations of plate and cutter by scheduling the feed along the tool path, is developed. The variation of the plate thickness due to machining and the partial disengagement of the plate and cutter due to excessive static deflections are considered in the model. The simulation system is proven in numerous peripheral milling experiments with both rigid blocks and very flexible cantilevered plates. . . (Cannot cut and paste the rest of the abstract…)

Abed (Engineering and Manufacturing Staff, Ford Motor Co., Dearborn, Michigan, USA), “Computer aided analysis of thin walled structural components subjected to axial and bending crush loads”, Eighth International Specialty Conference on Cold-Formed Steel Structures, St. Louis, Missouri, USA, November 11-12, 1986

ABSTRACT: An interactive computer program "SECOLLAPSE" has been developed to assist the designer in selecting the most efficient structural component to meet automotive requirements for crash strength and energy management. The program predicts the strength characteristics and loading history of general, thin walled plate-components, subjected to axial and/or bending crush loads. In the program the component section is divided into
several sub-elements according to its shape. Each sub-element is analyzed for elastic buckling, maximum strength, fold size and mode of collapse. Elements strength characteristics are determined based on the boundary condition (degree of restraint) and the applied stress pattern. The analytical prediction shows good correlation with the test data.

"Thin-walled structural elements: Classification, classical and advanced theories, new applications", Publisher and date are not given in the pdf file; the most recent reference is dated 2016. Perhaps this is a chapter in a book.

ABSTRACT: Thin structures were existing from the ancient time. From observations of the nature the people understood that thinner means lighter, but stiffness and stability problems arose. This was the starting point for the elaboration of theories analyzing these structures. At that time applications were limited to civil engineering. At present they are used in aerospace engineering as basic elements. Such structures are applied as a model of analysis in other branches too, e.g. mechanical engineering. With the necessity to substitute classical material by new (advanced) materials - instead of steel or concrete, now laminates, foams, nano-films, biological membranes, etc. are used. The new trends in applications demand improvements of the theoretical foundations of the plate and shell theories, since new effects (for example, transverse shear or surface effects) must be taken into account. This contribution is mainly an introduction to the CISM-Course SHELL-LIKE STRUCTURES: ADVANCED THEORIES AND APPLICATIONS. After some introduction to the history some examples concerning new applications are discussed. After that main directions in the theory of plates and shells are presented. Finally, various advanced theories are briefly introduced. Other advanced theories are presented in the following chapter.

H. Altenbach, V.A. Eremeyev, and N.F. Morozov. Linear theory of shells taking into account surface stresses. Doklady Physics,
INTRODUCTION: A structure can be classified as "thin-walled" if its thickness is much smaller than its other dimensions. In general, thin-walled structures possess a very high in-plane stiffness while their out-of-plane stiffness is very low. This property makes thin-walled structures very suitable for two purposes. Firstly, if the structure is designed such that the loading assesses mainly the in-plane stiffness, load-carrying constructions with very high stiffness-to-mass ratios can be achieved. Due to this property, thin-walled structures are used extensively in building and civil engineering constructions, aircraft, aerospace, shipbuilding and other industries. Secondly, the out-of-plane flexibility property of thin-walled structures allows to make mechanisms with relative large displacements while staying in the elastic domain. Applications can, for example, be encountered in suspension systems [138], deployable structures [125] and in Micro-Electro-Mechanical-Systems [114; 115].

The design of thin-walled structures encompasses a number of challenges. Firstly, thin-walled structures under compressive loading may become unstable, that is they buckle. Buckling often occurs at stresses much lower than the yield stress making the buckling strength one of the key design criteria. Secondly, thin-walled structures may be sensitive to geometrical imperfections (small deviations from the nominal shape) and loading imperfections. This can result in significant reductions of the maximum load carrying capacity of the imperfect structure with respect to the perfect one. Finally, out-of-plane displacements can rapidly become very large (in comparison with the thickness of the structure) resulting in the fact that geometrical nonlinearities can no longer be neglected during the analysis.

Although there are still some open issues, the analysis of the (nonlinear) response and buckling of thin-walled structured subjected to static loading (i.e. the situation in which transient inertia and damping forces may be neglected) is well established in engineering science [66]. However, in practise thin-walled structures are often subjected not only to a static load but also to a dynamic load. The resistance of structures liable to buckling, to withstand timedependent loading is addressed as the dynamic stability of these structures. The term dynamic stability will be further elucidated in Section 2.2. Now, two examples of dynamically loaded thin-walled structures will be discussed.

The first example comes from aerospace engineering and considers the case where a thin-walled structure acts as a (light-weight) load-carrying construction. The Vega is an expendable launch vehicle (ELV), used to place satellites into an orbit around the Earth, see Fig. 1.1. The satellite (the pay load) is placed in the top of the ELV and in four steps the vehicle is brought into the atmosphere. During each step, one stage of the ELV is ignited and after its fuel is burned it is separated from the rest of the vehicle using pyrotechnic charges. The first and second stage of the Vega are interconnected using a conical thin-walled interstage, see Fig. 1.2. The interstage has a maximum diameter of approximately 3 [m] and is constructed from curved aluminium panels with a thickness of approximately 6 [mm] in combination with ring stiffeners for extra stability [134]. A simplification of the mechanical loading of the interstage during the launch is shown in Fig. 1.3, i.e. the structure carries a rigid top mass (resembling the mass of the upper part of the launch vehicle) while being subjected to a base acceleration (resembling the longitudinal acceleration of the launch vehicle). During a typical launch, the longitudinal acceleration shows various static levels (with peak values up to 5.5 · g, where g = 9.81 [m/s²] denotes the gravitation constant) with on top significant dynamic fluctuations (order 1 · g) and shocks [9; 137]. The combination of the base acceleration and the top mass results in a (time-varying) compressive loading of the thin-walled interstage. Consequently, dynamic buckling of the interstage, but obviously also of other parts, is one of main issues during the design of such a launcher.

The next example illustrates how the (out-of-plane) flexibility property of thin-walled structures can be exploited to realize a flexible mechanism for adaptive optics on micro scale. In Fig. 1.4, a 3D self assembled

microplate suspended in two buckled beams is depicted [115]. The microplate has size 380 × 250 [μm] and can be electrostatically actuated using electrodes buried underneath the microplate. Before assembly, the structure is planar. Then, by using scratch drive actuators (SDA), the beams are forced to buckle and locked using a self-locking mechanism to make the buckled state permanent. This forces the microplate to lift out of the substrate plane, creating enough space for large rotations of the microplate. The buckled beams do not only lift the microplate but also act as elastic torsional hinges. In this manner, actuation of the microplate can be achieved with rotations up to ±15 degrees, while remaining in the elastic domain of the used material. During operation, the microplate is controlled to follow high speed prescribed motions, resulting in both torsional and transversal dynamic loading of thin buckled beams.

To obtain competitive designs for dynamically loaded thin-walled structures such as discussed above, it is vital to be able to understand, predict, and eventually optimize the dynamic stability behaviour of the structure. However, design strategies and fast (pre-)design tools for thin-walled structures under dynamic loading are still lacking. This can be partially explained by the involved computational complexity of the dynamic stability analysis, especially since in such analyses geometrical nonlinearities should be taken into account. Furthermore, in general time-dependent loads are described by multiple parameters (i.e. multi-parameter studies must be performed) and a wide variety in possible time-dependent loading types can be considered, like for example shock/impact loading, step loading, periodic loading or stochastic loading. Furthermore, although already many theoretical studies have been performed regarding dynamically loaded thin-walled structures [15; 77; 121], experimental validation of these results is scarce. Based on these observations, the objectives of this thesis are formulated in the next subsection.

**OBJECTIVE:** The research objective of this thesis is to develop (fast) modelling and analysis tools which give insight in the behaviour of dynamically loaded thin-walled structures. To illustrate and to test the abilities of the developed tools, a number of case studies are examined. The tools are developed for structures with a relatively simple geometry. The geometric simplicity of the structures allows to derive models with a relatively low number of degrees of freedom which are, therefore, very suitable for extensive parameter studies (as essential during the design process of a thin-walled structure). These models are symbolically derived via an energy based approach, using analytical expressions for the undeformed and deformed structural geometry. This approach has been implemented in a generic manner in a symbolic manipulation software package, such that model variations can be easily performed. For the analyses, both nonlinear static and nonlinear dynamic responses will be computed using numerical techniques in combination with the derived nonlinear models. The combination of the symbolic derivation of the model and the numerical techniques to obtain the solutions, is called a semi-analytical approach. Using this semi-analytical approach, the buckling of four structures due to both quasi-static loads and time-dependent loads (i.e. shock loading and harmonic loading) are thoroughly studied. These studies will include investigation of the effect of several parameter variations and the effect of small deviations from the nominal geometry. For validation, the semi-analytical results will initially be compared with results obtained from computationally much more demanding FEM analyses. However, more important, for two cases the semi-analytical results will also be compared with experimentally obtained results. For this purpose, a dedicated experimental setup will be realized.

due to the exact geometry description with NURBS, curvatures can be evaluated directly on the surface. Shell is mainly determined by its geometry and therefore a good geometric description is essential. Furthermore, functions. NURBS

In this thesis, the isogeometric analysis with the goal of merging design and analysis into one model by using a unified geometric representation. NURBS (Non-Uniform Rational B-Splines) are the most widespread technology in today’s CAD modeling tools and therefore are adopted as basis functions for analysis.

In this thesis, the isogeometric concept is applied to the analysis and shape optimization of shell structures. A new, rotation-free shell element is developed, using the Kirchhoff-Love shell theory and NURBS as basis functions. NURBS-based analysis provides advantages especially for shells, since the structural behavior of a shell is mainly determined by its geometry and therefore a good geometric description is essential. Furthermore, due to the exact geometry description with NURBS, curvatures can be evaluated directly on the surface without
rotational degrees of freedom or nodal directors.

Different examples show the good performance and accuracy of the method, for geometrically linear and nonlinear problems. Aspects concerning boundary conditions and the treatment of multiple patch structures are investigated, and solutions are proposed which allow the use of this method for a broad variety of problems. Furthermore, the developed shell formulation proves as very well suited for a direct integration into a CAD model, which is also realized in a commercial CAD software. The practical application of this integrated method for different examples also reveals problems and limitations of the present approach, which are discussed subsequently. Another goal of this thesis is to extend the isogeometric concept to shape optimization. After a brief review of shape optimization using CAD-based or FE-based design models, isogeometric shape optimization is introduced as a combination of both existing approaches which enhances flexibility in choosing the design space.

In the context of a cooperation project, the developed structural formulation is integrated into a fluid-structure interaction (FSI) environment and is applied to the three-dimensional FSI simulation of a wind turbine blade rotating in the air flow. This example shows the relevance of this method to large industrial applications.

Azhar Mahmood Nasir, “Axisymmetric shell structures for multi-use”, PhD Dissertation, School of Civil Engineering, Queensland University of Technology (QUT), Brisbane, Australia, March 2002

ABSTRACT: Shell structures find use in many fields of engineering, notably structural, mechanical, aerospace and nuclear-reactor disciplines. Axisymmetric shell structures are used as dome type of roofs, hyperbolic cooling towers, silos for storage of grain, oil and industrial chemicals and water tanks. Despite their thin walls, strength is derived due to the curvature. The generally high strength-to-weight ratio of the shell form, combined with its inherent stiffness, has formed the basis of this vast application. With the advent in computation technology, the finite element method and optimisation techniques, structural engineers have extremely versatile tools for the optimum design of such structures.

Optimisation of shell structures can result not only in improved designs, but also in a large saving of material. The finite element method being a general numerical procedure that could be used to treat any shell problem to any desired degree of accuracy, requires several runs in order to obtain a complete picture of the effect of one parameter on the shell structure. This redesign / re-analysis cycle has been achieved via structural optimisation in the present research, and MSC/NASTRAN (a commercially available finite element code) has been used in this context for volume optimisation of axisymmetric shell structures under axisymmetric and non-axisymmetric loading conditions.

The parametric study of different axisymmetric shell structures has revealed that the hyperbolic shape is the most economical solution of shells of revolution. To establish this, axisymmetric loading; self-weight and hydrostatic pressure, and non-axisymmetric loading; wind pressure and earthquake dynamic forces have been modelled on graphical pre and post processor (PATRAN) and analysis has been performed on two finite element codes (ABAQUS and NASTRAN), numerical model verification studies are performed, and optimum material volume required in the walls of cylindrical, conical, parabolic and hyperbolic forms of axisymmetric shell structures are evaluated and reviewed. Free vibration and transient earthquake analysis of hyperbolic shells have been performed once it was established that hyperbolic shape is the most economical under all possible loading conditions. Effect of important parameters of hyperbolic shell structures; shell wall thickness, height and curvature, have been evaluated and empirical relationships have been developed to estimate an approximate value of the lowest (first) natural frequency of vibration.

The outcome of this thesis has been the generation of new research information on performance characteristics of axisymmetric shell structures that will facilitate improved designs of shells with better choice of shapes and enhanced levels of economy and performance.

Ce Liang, “Analysis of crashworthiness of the dimpled thin-walled structures”, PhD Dissertation, University of Sussex (US), December 2017

ABSTRACT: Thin-walled structures are often used as kinetic energy absorbers in vehicular systems and infrastructure designs. In such applications, high specific energy absorption is usually desirable, because it is beneficial for weight reduction. The dimpling cold-roll metal forming process introduces dimpled geometry and increases the strength of sheet metal. This thesis aims to investigate the energy absorption characteristics of the dimpled thin-walled structures.

A finite element (FE) modelling analysis was performed using ANSYS Explicit Dynamics solver, to predict the response of dimpled structures to dynamic and quasi-static loads. A series of experimental tests were conducted and the FE method was validated through comparing the numerical and experimental results. To understand the response of the dimpled structural components to axial crushing loads, numerical simulations were performed. A parametric study on a key cold-roll forming parameter “forming depth” was carried out to evaluate its effects on the dimpled geometry and material properties. Through the parametric study, manufacturing parameters for the cold-roll forming process were suggested to improve yield strength and energy absorption performance of dimpled steel components. It was shown that the specific energy absorption can be increased by up to 16% after optimizing the forming depth.

To take the most advantage of the dimpled geometry, multi-layer dimpled thin-walled columns were analysed. The interlocking mechanism of dimpled plates were investigated and an empirical model was proposed to describe the interaction between dimpled plates. It was shown that a considerable amount of energy can be absorbed through the interaction between dimpled walls. The behaviour of dimpled columns under lateral impact loads was also investigated. It was revealed that the introduced dimpled geometry contributes to reducing the peak impact force without sacrificing the energy absorption capacity. However, this is only valid when at least one end of the dimpled thin-walled column is fully restrained.

“Composite plates modeling strategies for the estimation of transverse stresses”, ECCM16 – 16th European Conference on Composite Materials, Seville, Spain, 22-26 June 2014

ABSTRACT: The development of mechanical models that incorporate accurate estimations of the transverse normal and shear stress components are of notable importance in many engineering applications, and therefore
it has attracted the interest of the research community along the last decades. This is the case of debonding and delamination of composite laminates, in which these mechanical actions play a crucial role in the initiation and propagation of these damage mechanisms. In this contribution, the accuracy levels of some numerical techniques that are used to compute these stress components are assessed. Geometrically linear and non-linear benchmark problems are solved using such techniques, whose results are compared between them.

ABSTRACT: The paper presents the results of an experimental and numerical investigation of the deformation process of duraluminium plates under the action of a shock wave formed as a result of the explosion of a condensed explosive. The character of the deformation and destruction of the plate fixed along the perimeter is determined. It is shown that the plate is deformed according to the "envelope" scheme. The residual plastic deformation of the plate is determined. The shock wave load is described by semi-empirical dependences. The results of the calculations coincide with the experimental data.

ABSTRACT: Cold-formed thin-walled sections are prone to local buckling caused by residual stresses, geometrical imperfections and inconsistency of material properties. We present a real case of buckling failure and conduct a numerical and experimental study aimed to identify methods capable of predicting such failures. It is important because designers of structures are getting more FEA-oriented and tend to avoid lengthy procedures of cold-formed structures design. Currently adopted methods are complicated and require patience and caution from a designer which is reasonable in case of the most important structural members but not necessarily so in ordinary design. Since it is important, we offer an insight into several FEA and manual methods which were sufficient to predict the failure while remaining fairly simple. Using a non-uniform partial safety factor was still necessary. We hope that this paper will be of interest for people performing a lot of routine analyses and worrying about reliability of their computations.

ABSTRACT: In this study, geometrically nonlinear analysis of plate and shell structures is carried out by using a degenerated shell element. The present shell element is formulated by using the isogeometric concept. Reissner-Mindlin assumption is adopted in the element formulation where total Lagrange formulation is used. In particular, the positions of control points is consistently used to create the normal vector for the mapping between control points and associated points on real surface. The arc-length method is employed to handle the snap-through behaviour of shells. Several benchmark tests are tackled to verify the performance of the present shell element. From numerical tests, the present shell element can remove locking phenomena with the only use of refinement technique and it performs satisfactorily for both thin and thick plate and shell structures under geometrically nonlinear situations.

ABSTRACT: The term stability denotes an attribute of structure that can be characterized as an ability of the structure to remain in the equilibrium state. Stability of the bearing system is a crucial requirement when it comes to the safety of each building structure. In the presented work, the attention is paid to the analysis of an undesirable phenomenon of loss of stability. From the analysis of simple bar structures we gradually move to the stability analysis of planar structures (thin plates and shells). Among the substantial problems concerning the mechanism of stability loss of thin-walled structures belongs the snap-through of thin plate, of von Mises truss and of a shallow shell. Theoretical background of this phenomenon is analyzed in detail in this work. The geometrically nonlinear theory must be used to describe the post buckling effect of thin-walled structures. In the work, an incremental technique has been used (Euler) in combination with iteration procedures (Newton-Raphson). Effect of shape imperfections (called as initial imperfections) has been analyzed. In the primary analyses it was necessary to confirm the validity of some principles on mathematically simple models of bars. Subsequently, we proceeded with analysis of thin plates and shallow shells. In the case of plates loaded in compression, the post buckling behavior was analyzed. Our next objective was to investigate the stability problems of cylindrical shells and shells of translation. The above mentioned problems were examined using the computer software based on the Finite Element Method. The results of particular programs and computation approaches were analyzed and evaluated.

ABSTRACT: A cubic B-spline finite strip method (BFSM) is developed to analyze thin plates in bending. The basic mathematical relationships are derived for a direct stiffness formulation using a series type strip displacement function. Longitudinal behavior is modeled by a spline series in which unequal spline spacing is permitted. This feature allows local refinement of the discretization near patch and concentrated loads. Accuracy and convergence vis-à-vis alternative methods are compared. These include various finite element models, the conventional finite strip method and the BFSM with equally spaced splines. Comparisons show comparable accuracy with improved convergence. Oscillatory convergence due to Gibb's phenomenon, evident in some of the models, is avoided in the BFSM.

ABSTRACT: The studies on the long-term stability of composite plates and shells under limited creep carried out mainly by the research associates of the Institute of Polymer Mechanics are reviewed. The statement of the stability problems is discussed, according to which a viscoelastic structural member can be regarded as stable if
a disturbance in the form of a small initial deflection asymptotically tends with time to a small constant value. In the case of stability, as evidenced by experiments, the increase in the axisymmetric components of the initial deflection, dominating in the early stage, die down with time. On the contrary, the amplitudes of nonaxisymmetric initial imperfections grow at an increasing velocity. Analytical investigations show that the initial imperfections, when expanded into Fourier series, have a spectrum of short- and long-term critical forces. The deflection components having a critical force exceeding the external load are damped out, whereas those having a smaller critical force increase infinitely. The accelerated growth in the deflection, after a time, leads to transient buckling of the shell into a new stable equilibrium form. The problems of optimization of the structure and geometry of thin-walled composite constructions, with constraints on their long-term stability and critical time, are discussed.

ABSTRACT: This paper deals with the design of steel plate elements of rectangular industria

ABSTRACT: This paper deals with the design of steel plate elements of rectangular industrial ducts. Because of the practical aspect ratios and the stiffener arrangements, such a plate element is often treated as a long plate (one way slab), fixed supported at the edges and subjected to transverse pressure. The design pressure and the deflection limit determine the plate thickness and the stiffener spacing. Current design practice considers the geometrical nonlinearity, however, uses the strength criterion of first yield. This investigation postulates that consideration of partial yielding of the plate may result in an economical design option, while meeting the
serviceability criterion. The study is based on nonlinear finite element analyses of long plates subjected to increasing transverse pressure. Dimensionless parameters that characterize the behavior of such plates were identified and varied in a parametric study. Based on these analyses, design equations have been established for plate thickness and for stiffener spacing corresponding to three different scenarios namely: 0%, 16.5%, and 33% of through thickness partial yielding of the plate. Results show that allowing for 16.5% yielding results in 50% increase in stiffener spacing, at the expense of about 40% increase in deflections. Partially yielding plates can satisfy the serviceability limits states and can lead to economical stiffened plate systems for large rectangular industrial ducts.

ABSTRACT: Buckling and post-buckling are among the most important failure factors in thin walled structures. The load-carrying behavior of cylindrical thin-walled shell structures under external pressure load is strongly dependent upon the nature and magnitude of the initial imperfections. These imperfections are invariably caused by an assortment of manufacturing processes like installing or welding. One of the most important imperfections caused by welding that has been reported to have an essential detrimental effect on the buckling resistance of these shells under external pressure load is longitudinal imperfections. Buckling and post-buckling capacity of the shells depend on the H/R and t/ R ratios (H the height, R the radius and t the thickness of a cylindrical shell). The present work discusses the finiteelement models labeled as SS (Shallow Slim), DS (Deep Slim), ST (Shallow Thick) and DT (Deep Thick). The samples of first group are modified to include a line longitudinal imperfection, amplitudes of 0.5t, 1t, 2t, 3t, 4t and 8t in depth (t is the thickness of cylindrical shell). The results presented are in agreement with international codes and theories concerning buckling.

ABSTRACT: In this thesis both static and dynamic analyses of composite thin-walled structures are carried out. Most notably, the Dynamic Stiffness Method (DSM) has been extensively exploited to develop advanced formulations for plates and shells. In particular, the Dynamic Stiffness (DS) matrices have been developed for laminated composite plates and shells using Higher-order Shear Deformation Theory (HSDT) in order to investigate their free vibration behavior and buckling characteristics. First, the Governing Differential Equations (GDEs) of motion and associated natural Boundary Conditions (BCs) (Neumann-type) for the given displacement field are derived via Hamilton's principle for both composite plate and shell structures. In the case of composite plates, the DS matrices are formulated for both out-of-plane and in-plane deformations. The GDEs for each of the two cases are solved in Levy's form separately. Next the problems for both plates and shells are reduced to a system of ordinary differential equations which are then solved by using the classical exponential solution procedure.

Mart Heerschap, “Design of cut-outs in shell structures”, PhD dissertation, unknown university, 2018

ABSTRACT: Aircraft fuselages are inevitably weakened by a large number of cutouts. In particular large cut-outs in the pressure cabinet, like those for doors, remain highly fatigue sensitive. This is not only due to the fact that the cut-out causes a large stress concentration, but is also due to the use of the door in service. This considerably increases the chance of accidental damage. It is obvious, therefore, that the reinforcement around a cut-out must be designed with care. The large number of repair patches around doors and other large cut-outs, found on virtually all aircraft over a certain age, clearly shows that the currently used design methods are inadequate. An improved design method for cut-outs in pressurized aircraft fuselages is described in this thesis. The design aspect should be emphasized, because design is more than simply the availability of an appropriate analysis method. A design procedure may by definition include the sizing of the structure and, moreover, must provide the designer with sufficient information to understand its behaviour. The latter aspect is especially important, because this allows the designer to concentrate on the creative part of the design task. Reduction of the time taken in design is obviously important from an economical point of view. Besides economic...
advantages, reduction of the time taken in design is also important with respect to changes in design. A door together with its surrounding structure, is often redesigned to meet individual customer requirements and this redesign often has to be performed in a very short time. The design method presented in this thesis offers a procedure for the prediction and modification of the stresses around a cut-out by means of finite element analysis, optimization, sensitivity studies and "what-if" analysis. The design tool developed speeds up the design process by around an order of magnitude. The design method is applied to an existing aircraft and the results compared to experimental data. A parameter study is performed to identify the most effective members of the reinforcing structure.

ABSTRACT: An equivalent classical plate model of corrugated structures is derived using the variational asymptotic method. Starting from a thin shell theory, we carry out an asymptotic analysis of the strain energy in terms of the smallness of a single corrugation with respect to the characteristic length of macroscopic deformation of the corrugated structure. Without invoking any a priori assumptions, we obtained the complete set of analytical formulas for effective plate stiffnesses valid for both shallow and deep corrugations. These formulas can reproduce the well-known classical plate stiffnesses when the corrugated structure is degenerated to a flat plate. The extension-bending coupling stiffnesses are obtained the first time. The complete set of recovery relations are also derived for recovering the fields within the corrugated structure from the strains obtained in the equivalent plate analysis.

ABSTRACT: (Cannot cut and paste it)

ABSTRACT: A plate is an extended body where one of the dimensions is substantially smaller than the other two. The plates in three-dimensional (3D) thin-walled structures (called shells and folded-plate structures) can support both in-plane and out-of-plane loading. Furthermore, because the plates are thin, they lend themselves to approximation – while the structure may be three-dimensional, the local behavior is two-dimensional under plane stress. Plates in flexure are the two-dimensional equivalent of beams, and classical plate theory is the equivalent of the Bernoulli-Euler beam theory, whereas the in-plane or membrane behavior of plates is analogous to that of rods. We consider both of these separately.

We first develop the strong formulation for plates and present their spectral forms. It turns out, however, that very few strong-form solutions are available for arbitrary BCs, but there is one class with periodic BCs where very useful results can be obtained. We concentrate on these.
Flexural Behavior of Flat Plates
We develop a thin-plate model (called classical plate theory) that does not take the transverse shear deformation into account – this is therefore the plate counterpart of the Bernoulli-Euler beam. We could develop a model (called the Mindlin plate theory) that takes the shear deformation into account; however, it is worth keeping in mind that if shear effects in the plate might be important, then the plate should be modeled using the 3D solid Hex20 element.

“Folding to curved surfaces: A generalized design method and mechanics of origami-based cylindrical structures”. Scientific Reports, Vol. 6, Article ID 33312, 2016, doi: 10.1038/srep33312

ABSTRACT: Origami structures enrich the field of mechanical metamaterials with the ability to convert morphologically and systematically between two-dimensional (2D) thin sheets and three-dimensional (3D) spatial structures. In this study, an in-plane design method is proposed to approximate curved surfaces of interest with generalized Miura-ori units. Using this method, two combination types of crease lines are unified in one reprogrammable procedure, generating multiple types of cylindrical structures. Structural completeness conditions of the finite-thickness counterparts to the two types are also proposed. As an example of the design method, the kinematics and elastic properties of an origami-based circular cylindrical shell are analysed. The concept of Poisson’s ratio is extended to the cylindrical structures, demonstrating their auxetic property. An analytical model of rigid plates linked by elastic hinges, consistent with numerical simulations, is employed to describe the mechanical response of the structures. Under particular load patterns, the circular shells display novel mechanical behaviour such as snap-through and limiting folding positions. By analysing the geometry and mechanics of the origami structures, we extend the design space of mechanical metamaterials and provide a basis for their practical applications in science and engineering.

ABSTRACT: Origami engineering, which is the practice of creating useful three-dimensional structures through folding and fold-like operations applied to initially two-dimensional entities, has the potential to impact several areas of design and manufacturing. In some instances, however, it may be impractical to apply external manipulations to produce the desired folds (e.g., as in remote applications such as space systems). In such cases, self-folding capabilities are valuable. A self-folding material or material system is one that can perform folding operations without manipulations from external forces. This work considers a concept for a self-folding material system. The system extends the 'programmable matter' concept and consists of an active, self-morphing sheet composed of two meshes of thermally actuated shape memory alloy (SMA) wire separated by a compliant passive layer. The geometric and power input parameters of the self-folding sheet are optimized to achieve the tightest local fold possible subject to stress and temperature constraints. The sheet folding performance considering folds at different angles relative to the orientation of the wire mesh is also analyzed. The optimization results show that a relatively low elastomer thickness is preferable to generate the tightest fold possible. The results also show that the self-folding sheet does not require large power inputs to achieve an optimal folding performance. It was shown that the self-folding sheet is capable of creating similar quality folds at different orientations.

ABSTRACT: Four-fold-mechanisms, such as the Miura-Ori-pattern, and its possible combinations are investigated by completing the mathematical description of a thin paper model done by Haas [1], with influences resulting from the thickness of the plate material. Additionally, different planning and realisation factors are analysed, focusing particularly on the elasticity of the plate material, the folding pattern, the realistic simulation of the hinge position and its necessity of kinematical freedom, as well as the inner friction resistance, resulting from the deployment of the necessary drive mechanism. Possible combinations of single four-fold-mechanisms to larger patterns featuring these characteristics are investigated, taking into account the previously mentioned conditions for planning and realisation.

ABSTRACT: This paper deals with structural shape optimization of shells and folded plates using two-noded Mindlin-Reissner C(0) finite strips. The whole shape optimization process is carried out by integrating finite strip analysis, cubic spline shape definition, automatic mesh generation, sensitivity analysis and mathematical programming methods in an efficient way. Both thickness and shape variables defining the cross-section of the structure are considered. The objective is to minimize the strain energy with a constraint that the total material volume of the structure remains constant. It is observed that minimization of strain energy leads to optimum structures in which the deflections and stress resultants in the members are considerably reduced. This is illustrated using several examples. The relative contributions of the bending, membrane and shear strain energies are also monitored during the whole optimization process. It is found that most optimal shell and folded plate structures are membrane dominant.

Lorenzo Guiducci, John W.C. Dunlop and Peter Fratzl, “An introduction into the physics of self-folding thin structures”, Publisher and date not given in the pdf file; most recent reference is dated 2016

INTRODUCTION: Spontaneous folding of matter has long been the subject of disparate branches of research, from the earlier vitalistic view of Leibniz1 to the mathematical description of morphogenetic processes of D’Arcy Thompson.2 Today, scientific advancements have shown how folding is a common strategy adopted in biological systems to build up more and more complex structures – in proteins, from a peptide chain to a functional enzyme; in plants, from bud petals to a developed flower; in organisms, from layers of cells to diversified embryos. One might think that such folding processes require exceptionally complex biological machineries to orchestrate them. On the contrary, with this contribution, we will show that folding can result from remarkably simple processes – and equally applies to both natural and artificial systems. In the following we will introduce the reader to the necessary theoretical concepts that are needed to understand these phenomena, providing examples from the common experience enabling a more systematic understanding.

When we talk about self-folding3 thin structures we refer to a broad class of spontaneous shape changes (that is not caused by an external load) that occur in thin bodies. The adjective thin here means that a three-dimensional body has at least one dimension much smaller than the other; that is, a rod can be considered one-dimensional since it has two small dimensions; a plate instead is two-dimensional since it has one small dimension. In particular we will refer to bodies that can be considered two-dimensional, that is plates (which are flat) and shells (which are curved). As will become clear in section 1, the fact that plates (and shells) are thin is at the
base of the rich panorama of shape changes that are observed.
The goal of the present document is to provide an overview of some of the scientific literature dealing with shape changes in self-folding thin structures. Although these shape changes can be of a very different nature, size and origin – occurring in artificial as well as biological materials, and in systems that range from nanometer to centimeter sizes – all can be understood under some unifying concepts that will be introduced in the following. Thanks to our presentation, it becomes much easier to locate where research efforts have been focused until now and to identify new fields of interest that scientific research hasn’t addressed yet.

This document is organized as follows. In section 1 we introduce the reader to the basic concepts of the mechanics of a thin plate (the experienced reader can skip this part). In section 2 we will introduce many examples of self-folding systems, categorizing them on the base of how eigenstrains are distributed and oriented in the plate. In this section, we will discuss the folding (or more generally the morphing) of systems that: undergo confined expansion due to an attached elastic foundation (section 2.2); are subjected to the so-called edge growth (section 2.3); which change curvature (section 2.4). In section 3 we will give some concluding remarks on the present work.

displacements and stresses in the structures. Some parametric analysis is also presented.

ABSTRACT: Origami is an old art of paper folding. From mechanical point of view origami can be defined as a folded structure. In the present paper a comparative study of four origami inspired folded plate structures is presented. Longitudinal, facet, egg-box and Miura-ori origami modules are used for the analysis. The models are based on six-parameter shell theory with the use of the finite element method. Convergence analysis of each module is presented. Numerical study of roof folded plates in oriented to the comparison of maximal displacements and stresses in the structures. Some parametric analysis is also presented.

ABSTRACT: Folded Plates and spatial structures are adopted for construction of large span structures in which a large space is realized without columns as the structural components. In those cases, the structures are expected to resist against various design loads mainly through their extremely strong capability which can be acquired through in-plane or membrane stress resultants and this is just the reason by which they themselves stand for external loads without columns as their structural components in the large span structures. In civil engineering construction, folded plates are commonly used as roofing units. However, they are frequently subjected to dynamic loadings in their service life and hence, the knowledge of their dynamic behavior is important from the standpoint of analysis and design. To understand the performance and behavior of folded plate, the finite element modeling approach is a very important aspect. Finite Element Analysis is performed for both linear and non-linear problems to design and analysis evaluation situations. In this study the finite element modeling of multi bay cylindrical shell structures has been done to understand its performance during earthquake using SAP 2000 (version 14). The structure is idealized as an assemblage of thin constant thickness shell element with each element subdivided into 3 numbers of layers. The layered shell allows any number of layers to be defined in the thickness direction, each with an independent location, thickness, behavior, and material. This paper introduces the application of non-linear static and non-linear dynamic analysis of large-span RC spatial structure. In the present work an attempt has been made to convert the MDOF model of large span reinforced concrete shell structures into SDOF system using N2-method. With the help of this method, equivalent stiffness, mass and force can be obtained.

ABSTRACT: Folded plate structures should be redefined as form-resistant structures in which the folded-plate action is a combination of transverse and longitudinal beam action [1] p.264. The early generation of folded plate structure is marked with true folded plate structures. As the number and the variety of building form
increases, classification based on form took place and being developed. This leads to confusion and false interpretation of folded structures. The confusion is shown from building examples. Roofing with either steel or pre-stressed concrete trusses were classified as folded structures. Origami could lead to another confusion, because it could be applied either as a building structure or as a non-structural member, such as ceilings and awnings. Based on the case of Sydney Opera House, and on other misleading folded structure building examples, a conclusion to stop the usage of the term “folded structures” has been recommended. Another recommendation is to separate building form categories from building structure classification.

ABSTRACT: We discuss self-folding of a thin sheet by using patterned hydrogel bilayers, which act as hinges connecting flat faces. Folding is actuated by heterogeneous swelling due to different cross-linking densities of the polymer network in the two layers. Our analysis is based on a dimensionally reduced plate model, obtained by applying a recently developed theory [1], which provides us with an explicit connection between (three-dimensional) material properties and the curvatures induced at the hinges. This connection offers a recipe for the fabrication and design of the bilayers, by providing the values of the cross-linking density of each layer that need to be imprinted during polymerization in order to produce a desired folded shape upon swelling.

ABSTRACT: The discrete-Kirchhoff Mindlin quadrilateral (DKMQ) element has recently been developed for analysis of composite laminated plates. This paper presents further development of the DKMQ for analysis of composite laminated folded plates. In this development, a local coordinate system is set up for each element at its centroid. The DKMQ stiffness matrix is superimposed with that of the standard four-node plane stress quadrilateral element to obtain a 24-by-24 folded plate stiffness matrix in the local coordinate system. To avoid singularity of the stiffness matrix, a small stiffness coefficient is added in the entries corresponding to the drilling degrees of freedom. The local stiffness matrix and force vector are then transformed to the global ones and assembled. The accuracy and convergence of the folded plate element are assessed using a number of numerical examples. The results show that the element is accurate and converge well to the reference solutions.

INTRODUCTION: Membranes stretched in tension are found in a variety of large gossamer space structures in order to meet the requirements of future space exploration missions, including the JWST shield, solar sails, and space inflatable antenna reflectors. The surface of these membrane structures should be as wrinkle free, and crease free as possible, especially for the solar sails and the inflatable antenna reflectors [1]. The wrinkle is defined as an elastic response of a membrane due to the localized buckling in the compressed areas. It has been well studied by using the membrane method [2,3] and the thin shell method [4-6]. Large membrane structures must be folded for packaging or stowing before launching. These folding processes may create some permanent creases. The crease is defined as an inelastic deformation of the membrane characterized by a sharp cusp. The membrane creasing has not been well studied but the interest is growing[7,8]. In this paper, the wrinkling behavior of a rectangular creased membrane under shearing is analyzed by using the Direct Perturb-Force method[6] to deeply understand the wrinkle-crease interactions. The effects of the crease location on the wrinkling are also analyzed in the end.

“Wrinkling analysis of pre-stressed membranes using element free Galerkin method”, Publisher and date not given in the pdf file; the most recent reference is dated 2015

ABSTRACT: In the current study, element free Galerkin method, a meshless method, is proposed for wrinkling
analysis of pre-stressed membranes. The mathematical model for studying wrinkling of pre-stressed membranes is derived by considering the bending stiffness, though it is negligible. Moving least approximation for deflection is constructed by considering three degrees of freedom per node. Essential boundary conditions are imposed using scaled transformation matrix method. Initially, compression induced wrinkling of a homogeneous thin plate without pre-stress is solved to validate the method and then a pre-stressed homogeneous membrane is analyzed for both compression induced and shear induced wrinkling. Capabilities of proposed method for membrane analysis is compared with that of finite element method (FEM). Comparative study on wrinkling analysis using EFGM and different FEM element types in a FEM package shows that, in lower modes both methods shows satisfying consistency in eigenvalues with respect to total of number of nodes, while at higher modes EFGM shows better consistency than FEM. Further the study is extended to wrinkling of non-homogeneous membranes subjected to linearly varying in-plane load. The results obtained from EFGM analysis is compared and found to be matching well with those available in literature.

ABSTRACT: This paper is concerned with an efficient algorithm for the wrinkling with finite strains of very thin structures made of hyperelastic material. In this work, the problem of wrinkling is solved by directly minimizing the total potential energy of the structure. The numerical solution is carried out by means of an iterative method such as the conjugate gradient algorithm. Although the proposed approach is theoretically equivalent to the traditional finite element method, it proves to be an attractive alternative which is particularly efficient for thin wrinkled structures.

ABSTRACT: Wrinkling of thin membranes has become a huge concern in aerospace engineering due to the widespread of membrane structures in aerospace applications. The wrinkling of these lightweight structures is often observed and deteriorates their surface accuracy. Being thought that surface accuracy is a fundamental requirement in the manipulation and design of the membranes, it is necessary to evaluate the wrinkling of these materials in order to control and mitigate the wrinkling phenomenon. In this work, a study of the wrinkling phenomenon in thin rectangular sheets subjected to uniaxial tension is presented, including the wrinkle profile, the stress field and several parameters that influence this phenomenon. First, experimental tests on specimens with different thicknesses and plane dimensions are performed. Using a tri-dimensional digital image correlation technique (VIC-3D), the images of a rectangular Kapton HN sheet in tension are captured to investigate the evolution of the wrinkles, in terms of amplitude and wavelength. Then, a numerical study using the commercial finite element package ABAQUS is made based on the physical model of the membrane, with the aim to assess the growth, the evolution and the characteristics of the wrinkles. For that, a buckling and geometrically nonlinear analyses of the membranes are performed, using thin-shell elements. After that, the numerical validation of the results is made through the comparison with the numerical solutions available in published literature as well as the comparison with the experimental data obtained in this dissertation. Finally, some concluding remarks and future developments are described.

ABSTRACT: We present a new technique for simulating high resolution surface wrinkling deformations of composite objects consisting of a soft interior and a harder skin. We combine high resolution thin shells with coarse finite element lattices and define frequency based constraints that allow the formation of wrinkles with properties matching those predicted by the physical parameters of the composite object. Our two-way coupled model produces the expected wrinkling behavior without the computational expense of a large number of volumetric elements to model deformations under the surface. We use C1 quadratic shape functions for the interior deformations, allowing very coarse resolutions to model the overall global deformation efficiently, while avoiding visual artifacts of wrinkling at discretization boundaries. We demonstrate that our model produces wrinkle wavelengths that match both theoretical predictions and high resolution volumetric simulations. We also show example applications in simulating wrinkles on passive objects, such as furniture, and for wrinkles on faces in character animation.

This paper presents the development and evaluation of a wrinkling analysis procedure for anisotropic membrane. The procedure is based on a penalty-parameter modified material model and a nonlinear root finding to simulate the uniaxial stress state. The procedure was implemented in the ABAQUS finite element code as a user subroutine, and then applied to annular and square membranes. The wrinkling problems were also solved by shell element post-buckling analysis and the results were compared. The effect of anisotropy and unsymmetric loading on the wrinkling behavior was investigated.

ABSTRACT: Heterogeneous membrane with rigid elements has been extensively applied in flexible electronic systems and in aerospace structures. Here, we study the surface wrinkling of such heterogeneous membrane. Experiment, theoretical analysis and numerical simulation are performed to quantify the effect of rigid elements on the wrinkling pattern of the membrane. The characteristics of wrinkles related to the positions of rigid elements and stretching strain are investigated and the underlying mechanism is revealed. It is found that wrinkle patterns can be tailored by varying the positions of the rigid elements to achieve desired functions. Our results can provide insightful ideas to understand the wrinkling phenomenon of heterogeneous membranes and create novel wrinkle patterns in a controllable way.

ABSTRACT: A membrane, the two-dimensional analog of a string, is a thin-walled body that can only carry internal forces tangent to its deformed shape. Thus, a membrane is either a shell so thin that it is, essentially,
incapable of supporting stress couples or else it is a shell with sensible bending stiffness but which is subject to a combination of external loads and boundary/initial conditions which produce negligible bending. If we wish to distinguish between these two models, we shall refer to the former as a true membrane and to the latter as a (solution-dependent) shell-membrane. True membranes model certain biological tissues, inflatables, soap bubbles, shells subject to very high pressure and very large strains, and the like; shell-membranes model regions of shells that cannot undergo (nearly) inextensional bending and which are not too close to geometric or material discontinuities such as crowns of toroidal shells, cracks, or shell boundaries. Moreover, true membranes cannot support compressive stresses and thus may wrinkle whereas shell-membranes can resist this type of instability. In various parts of Section V.S we looked at the membrane limit of the simplified, nonlinear, small-strain, axisymmetric Reissner equations. In Section V.T, we developed the general theory of aximembranes undergoing large strains and gave many examples and references. In this chapter, we develop the general theory of membranes, including the subtheory of wrinkling, a topic both mathematically challenging and of growing applicability to natural and manufactured objects.

ABSTRACT: Al-polymer laminated membranes are widely used in large aerospace structures. When the laminated membranes are pressurized, wrinkles emerge, which have an important effect on the performance of the structures during operation. This paper describes the numerical simulation and experimental investigation of wrinkles in laminated membranes. The nonlinear postbuckling analysis method, based on laminated thin-shell elements, was used to simulate the onset, growth, and final configuration of wrinkles when laminated membranes are subjected to external loads. The simulations are conducted with the ANSYS finite element package. Changing regularities of number, wavelength, and range for the wrinkles during the onset and growth processes are investigated. The wrinkles of laminated membranes with different design parameters such as material selection, ply number, ply angle, and ply mode are predicted. Devices that can be used to clamp and load laminated membranes in several load cases were designed and developed. A 3D photogrammetry system was constructed to characterize wrinkling patterns of laminated membranes subjected to shear displacement loads. By comparing the results of numerical analysis and experimental results, the accuracy of the numerical analysis method was verified. This study work is expected to inform wrinkling simulation and shape control of aerospace laminated membrane structures.

ABSTRACT: The wrinkling characteristics of a rectangular graphene membrane under local tension are studied in this paper based on the continuum theory. The characteristics of the primary bifurcation and secondary wrinkling are studied to discover the physics of graphene wrinkling. The wrinkling geometry is predicted by a continuum theory model. The results reveal that the first wrinkle is formed at the primary bifurcation point. The non-uniform stretch-induced compressed effects, that originate from both the loaded portion and the clamped edges, buckle the graphene to form the first wrinkle. Secondary wrinkling is generated on the boundary of the wrinkled regions and the slack regions near the loaded portion in the post-wrinkling stage is the intrinsic nature of the wrinkling rupture and evolution of graphene. In addition, the length of the loaded portion and the aspect ratio of graphene have great effects on the wrinkling characteristics. These results are tremendously useful in understanding the intrinsic nature of the structural instability of graphene.

ABSTRACT: Wrinkling of thin membranes due to different in-plane loading and boundary conditions has drawn attention of researchers in structural engineering since the development of thin webs for early aircraft structures. More recently, prestressed lightweight membrane structures have been proposed for future space missions, for example solar sails, the next generation space telescope sunshield and space-based radar systems. These structures are often partially wrinkled during operation. The formation of wrinkles alters the load paths and the structural stiffness of the membranes. More importantly its occurrence degrades the surface accuracy of these structures, which is a key design parameter. This dissertation focuses on wrinkling of thin rectangular membranes subjected to uniaxial tension and investigates the onset and profiles of wrinkles using both experimental and numerical approaches. An optical method, which integrates fringe projection method with a uniaxial tension testbed, a LCD projector and a CCD camera, was developed in order to measure the full-field out-of-plane displacement of membranes, and an optical system was constructed including a uniaxial tension testbed, a LCD projector and a CCD camera. A series of uniaxial tensile tests were carried out on silicone rubber membranes of varying dimensions and aspect ratios in order to investigate the effect of geometric factors such as membrane dimension and aspect ratio on wrinkling onset; and a series of measurements were performed on each membrane at several desired strain levels to understand the evolution of the wrinkles, in particular wrinkle amplitude and wavelength. A numerical study was carried out using the commercial finite element software ABAQUS to further understand the important characteristics of wrinkling of thin membranes observed in the physical model. Geometrically nonlinear finite element models of membrane structures were constructed with thin-shell elements. A series of simulations were carried out for different membrane dimensions. The critical buckling load and buckling modes were predicted for each dimension using a pre-buckling eigenvalue analysis. The desirable buckling mode was selected and introduced into the structure as a geometric imperfection. The formation and growth of wrinkles were simulated in the post-buckling analysis. Finally, an idea of suppressing wrinkle instabilities of dielectric elastomer membranes using through-thickness electric field was proposed and verified in both experiment and numerical simulations.

ABSTRACT: Geometrically nonlinear shell finite element analysis has recently been applied to solar-sail membrane problems in order to model the out-of-plane deformations due to structural wrinkling. Whereas certain problems lend themselves to achieving converged nonlinear solutions that compare favorably with experimental observations, solutions to tensioned membranes exhibiting high stress concentrations have been difficult to obtain even with the best nonlinear finite element codes and advanced shell element technology. In this paper, two numerical studies are presented that pave the way to improving the modeling of this class of nonlinear problems. The studies address the issues of mesh refinement and stress-concentration alleviation, and the effects of these modeling strategies on the ability to attain converged nonlinear deformations due to
wringling. The numerical studies demonstrate that excessive mesh refinement in the regions of stress concentration may be disadvantageous to achieving wrinkled equilibrium states, causing the nonlinear solution to lock in the membrane response mode, while totally discarding the very low-energy bending response that is necessary to cause wrinkling deformation patterns. An element-level, strain-energy density criterion is suggested for facilitating automated, adaptive mesh refinements specifically aimed at the modeling of thin-film membranes undergoing wrinkling deformations.

ABSTRACT: As research on the applications of high-precision membrane structures develops, wrinkling has become a popular topic. Here, we present a new wrinkle-wave model to describe wrinkles more accurately. First, the characteristics of wrinkle-waves that result from radial tension stress applied at the vertex of a triangular structure were analyzed. However, for polygonal structures under more than two tensions, the influence of the other vertexes should also be considered. Therefore, by introducing a load ratio, we constructed a wrinkle-wave model of a square membrane structure subjected to corner forces. This model is applicable to various loading cases and polygonal membrane structures. Comparison among the results of the finite element analysis, and the experimental and analytical results showed that the proposed model more accurately described the wrinkling details and solved the problem of convergence that is encountered during finite element analysis.

ABSTRACT: A method to describe the stress situation in a wrinkled membrane is presented. In this paper it will be shown that a special deformation tensor can be chosen which leads to the correct stress state of a membrane after wrinkling when it is substituted in the constitutive equation. The method can be used for anisotropic membranes in geometrically and physically nonlinear analysis. The case of simple shear and stretching of a membrane is considered to illustrate the potency of the method.

ABSTRACT: We consider the point indentation of a pressurized elastic shell. It has previously been shown that such a shell is subject to a wrinkling instability as the indentation depth is quasi-statically increased. Here we present detailed analysis of this wrinkling instability using a combination of analytical techniques and finite-element simulations. In particular, we study how the number of wrinkles observed at the onset of instability grows with increasing pressurization. We also study how, for fixed pressurization, the number of wrinkles changes both spatially and with increasing indentation depth beyond onset. This ‘Far from threshold’ analysis exploits the largeness of the wrinkle wavenumber that is observed at high pressurization and leads to quantitative differences with the standard ‘Near threshold’ stability analysis.

ABSTRACT: Thin solar sail membranes of very large span are being envisioned for near-term space missions. One major design issue that is inherent to these very flexible structures is the formation of wrinkling patterns. Structural wrinkles may deteriorate a solar sail’s performance and, in certain cases, structural integrity. In this paper, a geometrically nonlinear, updated Lagrangian shell formulation is employed using the ABAQUS finite element code to simulate the formation of wrinkled deformations in thin-film membranes. The restrictive assumptions of true membranes, i.e. Tension Field theory (TF), are not invoked. Two effective modeling strategies are introduced to facilitate convergent solutions of wrinkled equilibrium states. Several numerical studies are carried out, and the results are compared with recent experimental data. Good agreement is observed between the numerical simulations and experimental data.

ABSTRACT: High strength thin-walled concrete-filled steel tubular (CFST) slender beam-columns may undergo local and global buckling when subjected to biaxial loads, preloads or cyclic loading. The local buckling effects of steel tube walls under stress gradients have not been considered in existing numerical models for CFST slender beam-columns. This thesis presents a systematic development of new numerical models for the nonlinear inelastic analysis of thin-walled rectangular and circular CFST slender beam-columns incorporating the effects of local buckling, concrete confinement, geometric imperfections, preloads, high strength materials, second order and cyclic behavior. In the proposed numerical models, the inelastic behavior of column cross-sections is simulated using the accurate fiber element method. Accurate constitutive laws for confined concrete are implemented in the models. The effects of progressive local buckling are taken into account in the models by using effective width formulas. Axial load-moment-curvature relationships computed from the fiber analysis of sections are used in the column stability analysis to determine equilibrium states. Deflections caused by preloads on the steel tubes arising from the construction of upper floors are included in the analysis of CFST slender columns. Efficient computational algorithms based on the Müller’s method are developed to obtain nonlinear solutions. Analysis procedures are proposed for predicting load-deflection and axial load-moment interaction curves for CFST slender columns under axial load and uniaxial bending, biaxial loads, preloads or axial load and cyclic lateral loading. The numerical models developed are verified by comparisons of computer solutions with existing experimental results and then utilized to undertake extensive
parametric studies on the fundamental behavior of CFST slender columns covering a wide range of parameters. The numerical models are shown to be efficient computer simulation tools for designing safe and economical thin-walled CFST slender beam-columns with any steel and concrete strength grades. The thesis presents benchmark numerical results on the behavior of high strength thin-walled CFST slender beam-columns accounting for progressive local buckling effects. These results provide a better understanding of the fundamental behavior of CFST columns and are valuable to structural designers and composite code writers.

“A comparative study between experimental and theoretical buckling load for hollow steel column”,
http://dx.doi.org/10.4314/ije.2018.v10i3.3

ABSTRACT: Hollow mild steel columns of same outer diameter and length but different wall thickness show
the buckling behavior in different manner in the fix-fix end condition. The behavior of the column is in good
agreement with Rankine’s formula. Additionally, there is a very strong relation between actual buckling load
and buckling load by Rankine’s formula. There is some difference between the theoretical and actual buckling
load which may be due to geometrical defect, crack generation, chemical composition and formation of
eccentricity. Columns show that the variation of differences between actual and theoretical buckling load with
respect to wall thickness is parabolic in nature.

ABSTRACT: This paper presents a new design approach for the stability design of thin-walled members. The proposed approach is based on the buckling modes and critical forces/moments determined by a linear buckling analysis performed on a regular shell finite element model. A fully automatic buckling mode identification technique is applied, by using the modal base functions of the newly proposed constrained finite strip method, where the various buckling types are separated by clearly defined mechanical criteria. The paper briefly summarizes the determination of modal base functions which then are used to approximate finite element displacement functions (i.e., buckling modes). The mode identification method provides the lowest critical values (forces or moments) to all the three characteristic buckling types: global, distortional and local, on the basis of which the buckling resistance can be calculated by using the design formulae of the direct strength method. The proposed new approach, which is potentially more general than any of the existing design approaches, is demonstrated on Z columns and beams with simple loading and boundary conditions. Critical values as well as resistances are calculated for some selected cases, the results are compared to those of another design method. The comparisons prove the applicability of the proposed procedure. Further research is necessary to extend the proposal for more general and more complex practical cases.

ABSTRACT: This paper presents an experimental investigation of short cold-formed lipped channel columns compressed between pinned ends. The short columns are subjected to pure axial compressive loading. Twelve column specimens are tested and the columns are categorised into three groups, depending on the length and thickness. The buckling modes of failure that occurred include local buckling and distortional buckling. A comparison of the experimental results with the loads predicted by the South African standard for the design of cold-formed steelwork (SANS 10162-2) shows that the code is not conservative enough to cater for these columns.

ABSTRACT: This work presents and discusses the buckling, post-buckling and ultimate behaviour of centrally compressed thin-walled T-sections members. It is firstly presented a brief literature review on recent studies involving this type of columns, and secondly the stability analysis of a wide range of members, with both ends fixed and different cross sections dimensions, obtain through GBTUL code, based on the Generalized Beam Theory - the study made possible to characterize the column buckling modes and select the dimensions, namely the length of the members. Then, the elastic and elasto-plastic post-buckling behaviours of short-to-intermediate columns with different values tensile stresses is analysed, using ABAQUS code. Finally, in a parametric study carried out to determine a wide range of ultimate load values, the quality of the Direct Strength Method (DSM) predictions to estimate the resistance of cold formed steel fixed-ended T section columns is assessed.

ABSTRACT: A review of literature on the area of the behaviour of thin-walled cold-formed steel structural members was carried out with an emphasis on the phenomenon of web crippling of beam members. Web crippling is a common mode of failure experienced by web elements of thin-walled beams under concentrated loads or reactions. Most of the studies done on web crippling behaviour are experimental and based on compression testing of beams to determine the ultimate web crippling strength. It has been identified that the theoretical investigation of web crippling behaviour is rather complicated due to localised collapse behaviour. However, some attempts have been made to develop theoretically based models to predict web crippling behaviour, and to obtain better understanding of the failure modes. Different theoretical studies, especially on elastic and plastic behaviour of plate elements were investigated with the intention of developing an analytical model to describe web crippling behaviour. It was found that almost all of the design codes around the world make design recommendations to predict the load at which web crippling would occur, based on equations obtained from web crippling tests conducted by various researchers.

ABSTRACT: The object of the research are short, thin-walled columns with an open top-hat cross section made of multilayer laminate. The walls of the investigated profiles are made of plate elements. The entire columns are subjected to uniform compression. A detailed analysis allowed us to determine critical forces and post-critical equilibrium paths. It is assumed that the columns are articulately supported on the edges forming their ends. The numerical investigation is performed by the finite element method. The study involves solving the problem of eigenvalue and the non-linear problem of stability of the structure. The numerical analysis is performed by the commercial simulation software ABAQUS. The numerical results are then validated experimentally. In the discussed cases, it is assumed that the material operates within a linearly-elastic range, and the non-linearity of the FEM model is due to large displacements.

Usage of cold formed steel structural components for buildings and structures is gaining popularity in India for a decade. Hot rolled steel member behaviour and design are well developed, whereas the cold formed steel member behaviour and design is not developed fully compared to the rest of the world. The Indian code for cold-formed steel design, IS 801 was revised during 1975, which is in line with 1968 edition of AISI standard. Bureau of Indian standards is in the process of revision of IS 801 to catch up with the latest developments and design methods with the other codes of practices in the world. As a background for the development of codal provisions, the design provisions developed in the various codes of practices have been reviewed and a comparative study has been carried out on design flexural strength of cold formed steel lipped channel sections. For this purpose, experimental results are collected from the literature. Based on the comparative study, direct strength method (DSM), which gives flexural strength closer to experimental results has been chosen for further parametric studies. There are several failure modes among which distortional buckling is one such failure mode that affects the strength of the section. In order to assess the influence of distortional buckling, a parametric study has been conducted by varying the lip depth, which is the influencing factor for distortional buckling strength. This paper presents the details of the studies carried out and the conclusions arrived.

ABSTRACT: Beam-column elements are defined as structural members subjected to a combination of axial and bending forces. Lateral torsional buckling is one of the major failure modes in which beam-columns that are bent about its strong axis may buckle out of the plane by deflecting laterally and twisting. This study presents a compact closed-form equation that it can be used for calculating critical lateral torsional-buckling load of beam-columns with monosymmetric sections in the presence of a known axial load. Lateral-torsional buckling behavior of beam-columns subjected to constant axial force and various transverse load cases are investigated by using Ritz method in order to establish proposed equation. Lateral-torsional buckling loads calculated by presented formula are compared to finite element model results. ABAQUS software is utilized to generate finite element models of beam-columns. It is found out that lateral-torsional buckling load of beam-columns with monosymmetric sections can be determined by proposed equation and can be safely used in design.

ABSTRACT: In this paper, one investigates the local-plate, distortional and global buckling behavior of thin-walled steel beams subjected to non-uniform bending moment diagrams, i.e. under the presence of longitudinal stress gradients. One begins by deriving a novel formulation based on Generalized Beam Theory (GBT), which (i) can handle beams with arbitrary open cross-sections and (ii) incorporates all the effects stemming from the presence of longitudinally varying stress distributions. This formulation is numerically implemented by means of the finite element method: one (i) develops a GBT-based beam finite element, which accounts for the
stiffness reduction associated to applied longitudinal stresses with linear, quadratic and cubic variation, as well as to the ensuing shear stresses, and (ii) addresses the derivation of the equilibrium equation system that needs to be solved in the context of a GBT buckling analysis. Then, in order to illustrate the application and capabilities of the proposed GBT-based formulation and finite element implementation, one presents and discusses numerical results concerning (i) rectangular plates under longitudinally varying stresses and pure shear, (ii) I-section cantilevers subjected to uniform major axis bending, tip point loads and uniformly distributed loads, and (iii) simply supported lipped channel beams subjected to uniform major axis bending, mid-span point loads and uniformly distributed loads — by taking full advantage of the GBT modal nature, one is able to acquire an in-depth understanding on the influence of the longitudinal stress gradients and shear stresses on the beam local and global buckling behavior. For validation purposes, the GBT results are compared with values either (i) yielded by shell finite element analyses, performed in the code ANSYS, or (ii) reported in the literature. Finally, the computational efficiency of the proposed GBT-based beam finite element is briefly assessed.

INTRODUCTION:
The beam has for many years been an important part of civil engineering structures. Successful design of structures involving beam elements requires a well-developed description of the beam behavior. This has been recognized by researchers and during the last century great emphasis has been given towards the establishment of linear as well as nonlinear beam theories. A review of some of the literature connected to beam theories is presented in Section 1.1. Driven by economic incentives such as increasing relative cost for materials, by the development of high-strength materials, and by the advancement in structural analysis and design, the trend has been towards the design and construction of increasingly more slender and flexible structures. An important component in this progress is the thin-walled beam. The double symmetric thin-walled beam has been used for many years while the use of thin-walled beams with arbitrary cross-sections is relatively recent. Using more slender and more flexible structures makes the stability problem essential in the design process. The stability behavior of symmetric beams, such as I- and H-profiles, has been examined for many years and leading to a general solution procedure where the stability failure is determined by considering an ideal structure. Possible precritical deformations are hereby neglected. In case of beam and frame structures with non-symmetric cross-sections the precritical deformations may be significant leading to a more complex behavior of the structure. This implies that the critical behavior is more complicated as for the symmetric structure. A rational utilization of these profiles therefore necessitates a detailed description of the stability problem. A theory is developed for beams of arbitrary shape, (Chapter 2). The beam is represented by a curve with a local set of base vectors fixed to the cross-section at each point of the curve. The generalized displacements are the translation vector for the curve and the rotation vector for the cross-sections. The equilibrium equations for the beam are reformulated as a virtual work equation, and this defines three strain components and three curvature components. The two shear strain components describe the difference between the tangent vector of the curve and the normal vector to the cross-section. It is important for a systematic derivation of the equations that all three rotation components are preserved as independent displacement parameters. If desired the Bernoulli hypothesis concerning the normality of the cross-sections can be introduced in the final equations. The warping effect, characteristic of thin-walled beams, is treated separately in order to preserve the generality. The general theory is specialised to stability analysis by considering a prebuckled/initial state, with prebuckling curvatures and stresses, and a neighbouring postbuckled state, (Chapter 3). The effect of prebuckling deformation is considered consistently by using the equilibrium equations of the initial state. Specialising the theory to thin-walled beams requires the appropriate constitutive equations. This is the subject of Chapter 4. A small strain deformation measure expressed by the generalized deformations is introduced and by energy principles the constitutive equations are developed. A brief discussion of energy principles is presented in Chapter 5 where also the transition from virtual work to potential energy or vice versa for the present formulation is considered. An example of the possibilities of the present formulation in a numerical context is given by the development of a two node beam element, (Chapter 6). The strain deformations are assumed negligible while the curvature contributions are retained in the formulation. This leads to a formulation in terms of the rotation components only. A link between displacements and rotations is obtained by introducing the zero strain condition via the
Lagrange Multiplier method. A mixed formulation is hereby obtained where linear shape functions can be used. This chapter serves as an introduction to the development of the incremental updated element considered in Chapter 8. Analytical stability analysis can be performed in a manageable way by some minor modifications of the general formulation, (Chapter 7). Neglecting strain deformations leads to a formulation expressed entirely in terms of the three rotation components. An asymptotic buckling and postbuckling theory is developed by means of a perturbation method. The asymptotic postbuckling behavior of a straight column in axial compression is considered for arbitrary cross-section parameters. The theory is also illustrated by analysing buckling and postbuckling of the beam in pure bending. The format of the results for this case are used to discuss the relation of the present general theory to previously published theories for simply curved beams. Further the governing parameters describing the initial postbuckling behavior are determined. Finally on the basis of the previous chapters a numerical formulation of the nonlinear stability problem is obtained in Chapter 8. The performance of the incremental updated Lagrangian two node hybrid element developed, is discussed by considering four canonical problems. The results strongly indicate that initial deformations and non-symmetric properties are essential for a proper determination of the critical load.

ABSTRACT: The paper deals with linear (eigen-buckling) and nonlinear buckling and post buckling analysis of thin-walled profiles made of FML type layered material. Considered profiles of open cross-section are subjected to axial compression. The analysis is performed with application of analytical and numerical method which results are compared with laboratory experiment. This multi-way approach gives the opportunity to improve both analytical and numerical models and solution methods which have been applied in our research team, with respect to current experiment results.

ABSTRACT: The finite element method is employed for the flexural-torsional linear buckling analysis of beams of arbitrarily shaped composite cross-section taking into account generalized warping (shear lag effects due to both flexure and torsion). The contacting materials, that constitute the composite cross section, may include a finite number of holes. A compressive axial load is applied to the beam. The influence of nonuniform warping is considered by the usage of one independent warping parameter for each warping type, i.e. shear warping in each direction and primary as well as secondary torsional warping, multiplied by the respective warping function. The calculation of the four aforementioned warping functions is implemented by the solution of a corresponding boundary value problem (longitudinal local equilibrium equation). The resulting stress field
is corrected through a shear stress correction. The equations are formulated with reference to the independent warping parameters additionally to the displacement and rotation components.

Schafer, "Development of a New Beam-Column Design Method for Cold-Formed Steel Lipped Channel Members" (2014). 22nd International Specialty Conference on Cold-Formed Steel Structures, St. Louis, Missouri, USA, November 5-6, 2014, https://scholarsmine.mst.edu/isccss/22iccfss/session04/1

ABSTRACT: The structural strength of cold-formed steel lipped channels under combined axial force and biaxial bending moments has been predicted by geometric and material nonlinear collapse analyses performed in ABAQUS and compared to both current, and a newly proposed, beam-column design method. The ABAQUS analyses utilizes a validated modeling protocol calibrated against previous testing by the authors, and including residual stresses and strains, and geometric imperfections; as well as, appropriate cross-section dimensions, member length, and boundary conditions. A total of 75 different lipped channel cross-sections have been selected and the capacity of the beam-column member has been examined under 127 combinations of actions in...
the P-M\textsubscript{1}-M\textsubscript{2} space (axial load, P, and major-axis, M\textsubscript{1}, and minor-axis, M\textsubscript{2}, bending moments). The results have been used to evaluate the current beam-column design method and validate a new Direct Strength Method (DSM) approach for cold-formed steel beam-columns. The newly proposed method provides means to incorporate more realistic stability analyses of cross-sections under the applied actions, where the current design methods include only a linear prediction of the combined actions using “column strength” and “beam strength” as anchor points. Correspondingly, the reliability of both current and newly proposed methods has been evaluated. The newly proposed extensions to the Direct Strength Method show a potential to realize a sizeable strength increase in many situations, and follow the overall trends in the data (P-M\textsubscript{1}-M\textsubscript{2} surface) well; however, additional advancement is needed to realize the complete benefits predicted in the finite element models.

“Experimental study of axially compressed cold formed steel channel columns”, Indian Journal of Science and Technology, Vol. 6, No. 4, April 2013

ABSTRACT: Analysis and design of axially compressed cold formed steel channel section presented in this paper was conducted through experimental study, design based on British standards and North American
Specification for the design of cold-formed steel structural members. More than 18 laboratory experiments were undertaken first on these steel channel columns under axial compression. A series of parametric studies were also carried out by varying the thickness and column length. All of these columns failed by local and distortional buckling. The test results were compared with American (AISI-2007) and British Standards (BS5950-Part5) for the design of cold-formed steel structural members. The details of this investigation and the outcomes are presented in this paper.

ABSTRACT: A column is a vertical compression member designed to transmit compressive loading. It is generally seen that when a slender member is loaded in compression, it will bow sideways or buckle, and if the load is then increased further the column will eventually fail in bending. Buckling is a mode of failure that is mainly observed in compression members due to structural instability. A pretwisted column has its strong flexural plane weakened and its weak flexural plane strengthened, leading to a favourable effect on buckling strength of the pretwisted column. A linear buckling analysis study was conducted for boxed and unboxed sections for columns with varying twist angles to study the effect of twist angle variation on improvement in buckling capacity. The studies reviewed that buckling capacity increased up to an optimum twist angle value
and further reduced. It was found that pretwisting is effective to increase the buckling capacity of columns.

ABSTRACT: This thesis presents a theoretical study into the behaviour of thin-walled metal tubes that are filled with elastic material. The study has considered the behaviour and design of concrete-filled steel columns by analysing the effect of the combined actions of axial compression and bending on closed stainless steel cross-sections with a concrete infill as well as the elastic buckling of square, circular and elliptical thin-walled steel tubes, when filled with elastic material. The elastic local buckling of a rectangular plate having four edges clamped and subjected to in-plane linearly varying uniaxial loading with and without juxtaposition with a rigid infill has also been studied. Concrete-filled composite columns find widespread use globally in engineering structures because of their optimal strength and ease of construction. Enhancing the strength of filled columns by utilising newer materials such as stainless steel or shape memory alloys for the skin of the cross-section of the column will increase the construction cost of the column. In order to circumvent this increased construction cost, or to minimise it, the metal skin should be as thin as possible. Members with thin-walled cross-section are prone to lateral torsional buckling, and in particular they are prone to local buckling, with the latter buckling mode playing an important role in the strength of a composite column with a concrete infill. The local buckling coefficient is enhanced by the provision of a rigid concrete infill, and efficient design must make use of this fact to minimise the cost of the skin. The initial portions of this thesis demonstrate the beneficial effects that the rigid concrete core has on the overall strength, and also on the local buckling behaviour of thin-walled metal tubes. The local buckling of the metal skin has been modelled in this thesis by using a Ritz-based energy method. In bi-lateral and uni-lateral buckling studies of rectangular plates, a more general trigonometric function has been selected by application of boundary conditions to the chosen shape function, with these boundary conditions being implemented to make the chosen shape function satisfy the edge conditions for the problem under consideration. The restraining medium is modelled as a tensionless foundation and this restraint condition is introduced through a penalty method formulation. Extensive comparative, convergence, and parametric studies have been carried out by considering a wide range of uni-laterally constrained plates. Following a concise review of the available literature, techniques for analysing the elastic local buckling of thin-walled square tubes, fully filled with elastic materials and subjected to concentric uni-axial compression, are formulated by means of a simple stiffness approach and a proper Ritz-based technique. This method is then extended to account for the local buckling of thin-walled circular and elliptical cylinders with elastic infill. By
representation of a proper trigonometric displacement function in the formulation which is capable of incorporating the effects of the penetration zone in a harmonic form, in addition to satisfying all the necessary boundary conditions, it is shown that the buckling solution reduces to a dimensionless representation for which the relevant geometrical and material properties that govern the local buckling coefficient can be identified. It was found that the provision of lightweight and low density infill is functional and attractive with respect to an increase in the efficacy of the restraint. A comparison was made, and good agreement was found to exist, between the results obtained from this study and results that are available in the literature. Finally, a strength to weight index is introduced that quantifies the enhancement in the local buckling coefficient for a number of materials with a wide range of stiffness and density. This index has potential applications for optimal design in aerospace and other specialized engineering applications.

ABSTRACT: Lateral buckling of a laminated composite beam with I-section is studied. A general analytical model applicable to the lateral buckling of a I-section composite beam subjected to various types of loadings is developed. This model is based on the classical lamination theory, and accounts for the material coupling for arbitrary laminate stacking sequence configuration and various boundary conditions. The effects of the location of applied loading on the buckling capacity are also included in the analysis. A displacement-based one-dimensional finite element model is developed to predict critical loads and corresponding buckling modes for a thin-walled composite beam with arbitrary boundary conditions. Numerical results are obtained for thin-walled angle-ply laminated composites under central point load, uniformly-distributed load, and pure bending. The effects of fiber orientation, location of applied load, and types of loads on the critical buckling loads are parametrically studied.

ABSTRACT: This article reports the results of an investigation on the effects of internal moments on the vibration behavior of thin-walled steel members. The analyses are based on the Generalized Beam Theory (GBT), a thin-walled bar theory accounting for cross-section in-plane deformations - its main distinctive feature is the representation of the member deformed configuration by means of a linear combination of cross-section
deformation modes, multiplied by their longitudinal amplitude functions. The study concerns a simply supported T-section (with unequal flanges) members exhibiting a wide range of lengths and subjected to uniform internal moment diagrams - their magnitudes are specified as percentages of the corresponding critical buckling values. After providing a brief overview of the main concepts and procedures involved in performing a GBT-based structural analysis, the vibration behavior of load-free and loaded T-section members is addressed - the influence of the applied loadings is assessed in terms of (i) the fundamental frequency difference and (ii) the change in the corresponding vibration mode shape. For validation purposes, some GBT results are compared with values yielded by shell finite element analysis performed in the codeABAQUS (Simulia, 2008).

Demao Yang, “Compression stability of high strength steel sections with low strain-hardening”, PhD dissertation, School of Civil and Mining Engineering, University of Sydney, Australia, 2003

**ABSTRACT:** Thin-walled steel sections made from high strength thin cold-reduced G550 steel to Australian Standard AS 1397-1993 under compression are investigated experimentally and theoretically in this thesis. This thesis describes three series of compression tests performed on box-section stub columns, box-section long columns and lipped channel section columns cold-formed from high strength steel plates in 0.42 mm or 0.60 mm thickness with nominal yield stress of 550 MPa. The tests presented in this thesis formed part of an Australian Research Council research project entitled "Compression Stability of High Strength Steel Sections with Low Strain-Hardening". For the fix-ended stub column tests, a total of 94 lipped-square and hexagonal section stub columns were tested to study the influence of low strain hardening of G550 steel on the compressive section capacities of the column members. For the pin-ended long column tests, a total of 28 box-section columns were tested to study the stability of members with sections which undergo local instability at loads significantly less than the ultimate loads. For the fix-ended lipped channel section columns, a total of 21 stub and long columns were tested to study the failure resulting from local and distortional buckling with interaction between the modes. A numerical simulation on the three series of tests using the commercial finite element computer program ABAQUS is also presented as part of this thesis. The post-buckling behaviour of thin-walled compression members is investigated. The effect of changing variables, such as geometric imperfections and end boundary conditions is also investigated. The ABAQUS analysis gives accurate simulations of the tests and is in good agreement with the experimental results. Theoretical studies using finite strip methods are presented in this thesis to investigate the buckling behaviour of cold-formed members in compression. The theoretical studies provide valuable information on the local and distortional buckling stresses for use in the interaction buckling studies. The finite strip models used are the semi-analytical and spline models. As expected from the stub columns tests, the greatest effect of low strain hardening was for the stockier sections where material properties play an important role. For the more slender sections where elastic local buckling and post-local buckling are more important, the effect of low strain hardening does not appear to be as significant. The pin-ended and fix-ended long column tests show that interaction, which is between local and overall buckling in the box sections, and between local and distortional buckling in the open channel sections, has a significant effect on their member capacities. The results of the successful column tests and ABAQUS simulation have been compared with the design procedures in the Australian/New Zealand Standard for Cold-Formed Steel Structures (AS/NZS 4600) and the North American Specification for Cold-Formed Steel Structural Members prepared by the American Iron and Steel Institute. The stub column tests show that the current design rules give too conservative predictions on the compressive section capacities of the column members; whereas the long column tests show that the current column design rules are unconservative if used in their current form for G550 steel. Three design proposals are presented in this thesis to account for the effects of high strength thin steels on the section and member capacities.

ABSTRACT: This paper deals with seismic design and retrofit of thin-walled steel tubular columns supporting highway bridge superstructures. The basic characteristics of the thin-walled steel tubular columns are noted and the importance of various retrofit techniques in improving strength and ductility capacity of such structures is explained. A seismic design method for ultimate strength and ductility evaluation of the retrofitted, thin-walled, steel tubular beam-columns is presented. The application of the method is demonstrated by comparing the computed strength and ductility of some cantilever columns with test results. The method is applicable for both the design of new and retrofitting of existing thin-walled steel tubular columns. The effects of some important parameters such as width-to-thickness ratio, column slenderness ratio, height of infill concrete, residual stress, arrangement of additional longitudinal stiffeners and energy absorption segment on the ultimate strength and ductility of thin-walled steel tubular columns are presented and discussed.

ABSTRACT:

In this work, non-uniform steel members with or without initial geometrical or loading imperfections, that are loaded by axial forces applied concentrically or eccentrically and by concentrated moments applied at the ends or at intermediate points, are studied. More specifically, steel members with varying cross-sections, tapered or stepped or members consisting by two different tapered parts are considered. The formulation presented in this work is based on solving the governing equation of the problem through a numerical method where the eigenshapes of the member are employed. A failure plasticity criterion is introduced for members especially the short ones that will never reach the elastic critical buckling load. Although only the simply supported beam-column case is studied herein, it is obvious that the method can be extended to multi-span beams and frames, by employing the corresponding eigenshapes. Useful diagrams are presented for both the critical buckling loads and the equilibrium paths showing the influence of the main characteristics of the beam-column.

“Buckling and ultimate failure of thin-walled pultruded composite columns”, Polymers and Polymer Composites, Vol. 12, No. 6, 2004

ABSTRACT: This paper presents the results of an investigation on the buckling behavior of concentrically loaded thin-walled pultruded fiber reinforced polymer (PFRP) composite columns. Both open- and closed-web columns were evaluated. Finite element (FE) analysis and theoretical predictions are presented and correlated with experimental data. Good agreement between theoretical, analytical and experimental results was achieved. The paper also presents design guidelines to determine the bending stiffness and the critical buckling load for pultruded composite columns. In addition, a discussion on the axial strength of unidirectional PFRP columns and identification of different modes of failure are presented.

“Distortional buckling of cold-formed steel columns”. Final Report to the American Iron and Steel Institute: Washington (DC). 2000; Appendix A to that report:
Benjamin Schafer and Gregory Hancock, “A detailed history of distortional buckling of columns”
ABSTRACT: Research in the behavior of cold-formed steel columns spans approximately fifty years. Through that time distortional buckling, under many different names, has come in and out of the spotlight. This brief account highlights the major experimental work in cold-formed steel column research. Theoretical trends are also briefly mentioned, particularly as they relate to distortional buckling. Though distortional buckling in beams and columns is intimately tied together an attempt is made to focus only on the column research.

A parametric study was then performed using the numerical model and interaction diagrams for the investigated and strength of thin structures. The model considers both the material and geometric nonlinearities. The model results were first verified against some of the currently available experimental results. A parametric study was then performed using the numerical model and interaction diagrams for the investigated beam-columns have been presented. The effects of the web depth-to-thickness ratio, flange outstand-to-thickness ratio and bending moment-to-normal force ratio on the ultimate strength of thin-walled I-section
beam-columns were scrutinized. The interaction equations adopted for beam columns design by the NAS
(North American Specifications for the design of cold formed steel structural members) have been critically
reviewed. An equation for the buckling coefficient which considers the interaction between local buckling of
the flange and the web of a thin-walled I-section beam-column has been proposed.

L. Pesic, D. Lane and G. Turkalj (Department of Engineering Mechanics, Faculty of Engineering, University of
Rijeka, Vukovarska, Rijeka), “Non-linear thermal buckling analysis of thin-walled beam structures”,

ABSTRACT: The paper presents an algorithm for thermal buckling analysis of thin-walled beam-type
structures. One-dimensional finite element is employed under assumptions of large displacements, large rotation
effects but small strains. Stability analysis is performed in load deflection manner using co-rotational
formulation. The cross-section mid-line contour is assumed to remain not deformed in its own plane and the
shear strains of middle surface are neglected. The material properties of the beam are temperature-dependent.

Results are validated on test examples.

Li Bai, “Interactive buckling in thin-walled I-section struts, PhD dissertation, Dept. of Civil and Environmental Engineering, Imperial College London, May 2014

ABSTRACT: Compression members, made from slender metallic plate elements, are prone to a wide range of
different elastic instability phenomena. A thin-walled I-section strut, made from a linear elastic material, can
suffer from the nonlinear interaction between a global (Euler) buckling mode, and a local flange plate buckling mode. The interactive buckling behaviour is usually much more unstable than when the modes are triggered individually and hence significantly reduces the load-carrying capacity of real struts. The current work focuses on such a problem using an analytical approach, the methodology of which has been well established in previous works on sandwich struts and I-section beams. An analytical model that describes the interactive buckling of a thin-walled I-section strut under pure compression based on variational principles is presented. Analytical formulations combining the Rayleigh–Ritz method and continuous displacement functions are presented to derive a series of systems that comprise differential and integral equilibrium equations for the structural component. Solving the systems of equations with numerical continuation reveals progressive cellular buckling (or snaking) arising from the nonlinear interaction between the weakly stable global buckling mode and the strongly stable local buckling mode. The resulting behaviour is highly unstable and when the model is extended to include geometric imperfections it compares excellently with some recently published experiments. Imperfection sensitivity studies reveal high sensitivity to both global and local imperfection types. The worst forms of local imperfection are identified in terms of the initial wavelength, amplitude and degree of localization. The effect of the varying rigidity of the joint of the section web and flanges is also studied and a rapid erosion of the cellular buckling response is revealed with increasing rigidity of the flange–web joint. A shell-based nonlinear finite element model is presented, primarily for validation purposes. The results from the analytical and finite element models show a good comparison, particularly for higher rigidities of the flange–web joint. A parametric study is conducted for two limiting cases, where the flange–web joint is assumed to be fully pinned or fully rigid. For a chosen set of geometries, the most undesirable interactive region is identified for both global and local slendernesses, in terms of the strut length and the flange width respectively. Practical implications are discussed in terms of the idealized buckling design curve. An analytical framework for the structural analysis of the thin-walled I-section struts that exhibit the nonlinear interaction of a global and a local buckling mode, including cellular buckling, has therefore been established.

Wadee, M. A. 2000. Effects of periodic and localized imperfections on struts on nonlinear foundations and compression sandwich

ABSTRACT: This paper deals with a theoretical and a numerical analysis of tapered beam-columns subjected to a bending moment and an axial force. A standard FEM code COSMOS/M has been used for a numerical estimation of a critical load multiplier. It has been assumed that the critical force of an axially loaded tapered column could be calculated in an analogous way as for uniform member just with an additional correction factor $\eta$. Similarly, a critical bending moment of the tapered column subjected to a pure bending could be determined by using a correction factor $\mu$. A large number of simulations carried out within a wide range of the ratios of second moments of area allowed to determine the proper values of these two factors. For practical engineers, solution of such kind of problems can be easier when an equivalent cross-sectional height $h_{eq}$ is used.

ABSTRACT: A fully nonlinear theory of a three-dimensional thin-walled beam, in arbitrary rectangular coordinates with the pole of the sectorial area at an arbitrary point and the origin of the sectorial area at an arbitrary point of the beam section, is developed to incorporate transverse shear, torsion-induced warping, and local-buckling-induced cross-section distortion. Based on a geometrically-exact description of the kinematics of deformation, this theory allows large deformation and large overall motion with a general out-of-plane warping function and a general in-plane distortion function. The present theory can exactly reduce to the classical Vlasov theory for vanishing shearing and cross-section distortion in the case of small deformation. The nonlinear weak form of the governing equations of equilibrium is constructed and the linearization of the weak form is derived. A finite element code is developed to implement this generalized thin-walled beam element. The results given by the post-buckling analysis are compared with numerical and/or experimental results to investigate the local buckling effect on the member behavior.

Cold-Formed Steel

[80] Yu, F. (2001). Design of Cold-Formed Steel Plain Channels, Progress Report: Project No CF9501, Department of Civil Engineering, Cornell University

ABSTRACT: This paper presents a performance-based analysis (PBA) technique based on fiber element formulations for the nonlinear analysis and performance-based design of thin-walled concrete-filled steel tubular (CFST) beam-columns with local buckling effects. Geometric imperfections, residual stresses and strain hardening of steel tubes and confined concrete models are considered in the PBA technique. Initial local buckling and effective strength/width formulas are incorporated in the PBA program to account for local buckling effects. The progressive local buckling of a thin-walled steel tube filled with concrete is simulated by gradually redistributing normal stresses within the steel tube walls. Performance indices are proposed to quantify the section, axial ductility and curvature ductility performance of thin-walled CFST beam-columns under axial load and biaxial bending. Efficient secant algorithms are developed to iterate the depth and orientation of the neutral axis in a thin-walled CFST beam-column section to satisfy equilibrium conditions. The analysis algorithms for thin-walled CFST beam-columns under axial load and uni- and biaxial bending are presented. The PBA program can efficiently generate axial load–strain curves, moment–curvature curves and axial load–moment strength interaction diagrams for thin-walled CFST beam-columns under biaxial loads. The proposed PBA technique allows the designer to analyze and design thin-walled CFST beam-columns made of compact or non-compact steel tubes with any strength grades and normal and high-strength concrete. The verification and applications of the PBA program are given in a companion paper.

ABSTRACT: Use of thin-walled steel sections in structures represents a trend further in the exploitation of structural form from its early ponderousness to the present day's trend towards tenuity. In the past seventy years, extensive experimental and analytical research has been carried out to examine the behavior of thin-walled
structures containing openings. The experimental results have not been fully utilized by other researchers. As part of this review, an endeavor is made to cluster the experimental and analytical results with particular importance on plates, beams and plate girders and compression members and cellular structures containing perforations as an elucidative database using a handy spreadsheet program written in Visual Basic.

ABSTRACT: This paper is concerned with the application of the direct strength method to equal angle section beam-columns with locally unstable legs. In contrast to existing design methods, which independently determine the compression and bending capacities and use an interaction equation to combine these, the direct strength method determines the elastic local buckling stress for the actual stress distribution resulting from the combined action of compression and bending, and incorporates the elastic buckling stress into a direct strength equation for beam-columns. In applying the method to equal leg angles, the torsional buckling mode is ignored when determining the overall buckling capacities, since it is accounted for through the local buckling mode, and the shift of the effective centroid is incorporated as an additional loading eccentricity. The shift in the effective centroid resulting from local buckling is determined from the actual stress distribution, as obtained using Stowell’s classical solution, in place of an effective cross section. The predicted strengths are conservative compared to tests on slender equal angle columns, and are shown to accurately predict the variation in load with applied loading eccentricity.

Benjamin W. Schafer, “Cold-formed steel structures around the world: A review of recent advances in applications, analysis and design”, Steel Construction, 2011; (4) 3, https://doi.org/10.1002/stco.201110019

ABSTRACT: The objective of this paper is to provide a brief review of recent (over approximately the last five years) advances in the application, analysis and design of cold-formed steel structures. Attention here is focused on load-bearing cold-formed steel structures; as opposed to secondary systems, curtain walls, etc. Cold-formed steel applications continue to advance in three primary categories: framing, metal buildings, and racks. Examples largely derived from the author’s experiences in North America are used to illustrate the applications. The behaviour of cold-formed steel structures can be complicated due to the thin-walled nature of the sections; thus, analysis advances are required. Recent work in Generalized Beam Theory and the constrained Finite Strip Method demonstrate that, at least when it comes to thin-walled members, significant advances in structural analysis are still possible and desirable. Design of cold-formed steel structures continues to see significant improvements and refinements. Recent efforts related to the Direct Strength Method of design are highlighted, including novel extensions from the member to the system level. Finally, similar to many other areas of structural engineering, seismic engineering has motivated notable advances in applications, analysis, and design. For cold-formed steel structures these advances are reviewed to demonstrate current progress and future directions in this important area.

ABSTRACT: A review of papers that investigate the static and dynamic coupled buckling and post-buckling behaviour of thin-walled structures is carried out. The problem of static coupled buckling is sufficiently well-recognized. The analysis of dynamic interactive buckling is limited in practice to columns, single plates and shells. The applications of finite element method (FEM) or/and analytical-numerical method (ANM) to solve interaction buckling problems are on-going. In Poland, the team of scientists from the Department of Strength of Materials, Lodz University of Technology and co-workers developed the analytical-numerical method. This method allows to determine static buckling stresses, natural frequencies, coefficients of the equation describing the post-buckling equilibrium path and dynamic response of the plate structure subjected to compression load and/or bending moment. Using the dynamic buckling criteria, it is possible to determine the dynamic critical load. They presented a lot of interesting results for problems of the static and dynamic coupled buckling of thin-walled plate structures with complex shapes of cross-sections, including an interaction of component plates. The most important advantage of presented analytical-numerical method is that it enables to describe all buckling
modes and the post-buckling behaviours of thin-walled columns made of different materials. Thin isotropic, orthotropic or laminate structures were considered.

ABSTRACT: A new analytical model has been developed for a study of the response of thin-walled beam-columns having doubly symmetric cross sections. The novel features of the model are that: (1) It incorporates the interaction of overall buckling/bending with two companion local modes; (2) it accounts for the phenomenon of amplitude modulation; and (3) it can model any set of realistic end conditions. These features are a result of an innovative combination of the finite strip and finite element techniques. The model has been tested for numerical convergence and against the available results on square box columns. A small number of examples have been studied. These relate to the performance of eccentrically loaded columns and single story frames. Also, the vital necessity of considering amplitude modulation in thin-walled beam columns has been brought out.

ABSTRACT: Features of the phenomenon of interactive buckling of thin-walled columns are briefly reviewed. The theoretical results are compared with the recent test results from University of Sydney and earlier results from Cornell University. The agreement is very good indeed. The role of imperfections in producing scatter in the prediction of the ultimate capacity of the columns is illustrated. Design procedures, one developed at Cornell University in the seventies and the other recommended by the new American Iron and Steel Institute Code, are examined in the light of the new results. In order to account for the interaction of plate elements, it is suggested that exact local critical stress be used in the effective width formula. To obtain a reliable and safe estimate of the column strength, it is proposed that the collapse load given by the design methods be multiplied by an appropriate factor. This factor must be a function of the key parameters governing the problem. A statistically derived expression for this factor is also suggested.

ABSTRACT: Many review articles were published on free vibration and buckling of laminated composites, sandwich plates, and shells. The present article reviews the literature on the buckling and free vibration analysis of shear deformable isotropic and laminated composite sandwich plates and shells using various methods available for plates in the past few decades. Various theories, finite element modeling, and experimentations have been reported for the analysis of sandwich plates and shells. Few papers on functionally graded material plates, plates with smart skin (electrorheological, magnetorheological, and piezoelectric), and also viscoelastic materials were also reviewed. The scope for future research on sandwich plates and shells was also accessed.

ABSTRACT: This paper presents the state of art in the field of composite shells with focus on stress analysis, buckling and post-buckling responses under mechanical and thermal loading. Many researchers have investigated the buckling and post-buckling responses of cylindrical, conical, spherical, thin and thick composite shells with single and doubly curved shells under mechanical and thermal loading. From the literature it can be inferred that hydrostatic pressure, axial compression and thermal environment influence the buckling behavior of laminated composite shell significantly. An effort is taken to review the research on buckling and post-buckling responses of cylindrical and conical shaped shells under mechanical and thermal loading and their behavior during buckling and post-buckling conditions.

ABSTRACT: The paper is devoted to cold-formed thin-walled channel beams with open or closed flanges. The global–local buckling and optimization of these beams are described. The review includes simple analytical description and calculations, numerical analysis, and the laboratory tests of selected beams. The buckling problems for flanges and webs of thin-walled beams are described in detail. Additionally, an objective comparison of the beams of different cross sections is presented. A quality measure of thin-walled beams is proposed. Comparison of selected thin-walled beams with use of the quality measure is presented in figures.

ABSTRACT: Thin films deposited on substrates are usually submitted to large residual compression stresses, causing delamination and buckling of the film into various patterns. The present study is focused on the different equilibria arising on strip-shaped delaminated areas. The three most common types of buckling patterns observed on such strips are known as the straight-sided wrinkles, bubble pattern, and telephone cord blisters. The stability of those equilibria as a function of the two stress components of the loading is investigated. The Föppl–Von Karman model for elastic plates is used for theoretical aspects. The post-critical equilibrium paths of the buckling patterns are investigated numerically by means of the finite-element method. The substrate is assumed to be rigid and the contact to be frictionless. The equilibrium solutions can be classified into families of homologous equilibria allowing the identification of dimensionless parameters for the study of stability. A mapping of the different stable post-critical equilibria is given. It is shown that the straight-sided wrinkles and the bubbles are associated with anisotropy of stresses and/or of elastic properties, whereas the telephone cords are stable at high isotropic stresses. The morphological transitions are experimentally evidenced by in situ atomic force microscopy observations of a nickel 50–nm-thick film under stress.

ABSTRACT: Tubular construction is synonymous with modern architecture. The familiar range of tubular sections – square, rectangular and circular hollow sections – has been recently extended to include elliptical hollow sections (EHSs). Due to differing flexural rigidities about the two principal axes, these new sections combine the elegance of circular hollow sections with the improved structural efficiency in bending of rectangular hollow sections. Following the introduction of structural steel EHSs, a number of investigations into their structural response have been carried out. This paper presents a state-of-the-art review of recent research on EHSs together with a sample of practical applications. The paper addresses fundamental research on elastic local buckling and post-buckling, cross-section classification, response in shear, member instabilities, connections and the behaviour of concrete-filled EHSs. Details of full-scale testing and numerical modelling studies are described, and the generation of statistically validated structural design rules, suitable for incorporation into international design codes, is outlined.

ABSTRACT: The enabling emerging technologies such as nanotechnology increased the demand for small-size devices. The proper understanding of the nonclassical behavior of nanostructures is key for the design of these devices. As a result, the static and dynamic behavior of nanoscale beam structures has received a great attention in the past few years. This review aims at directing the light to research work concerned with bending, buckling, vibrations, and wave propagation of nanobeams modeled according to the nonlocal elasticity theory of Eringen. Due to the large body of references found in the literature, the authors chose to briefly present the key findings and challenges and direct light to possible future work. This review does not intersect with recent relevant reviews, which reflects its significance to readers.

ABSTRACT: Buckling behavior of tubulars inside wellbores is the major subject of many articles. This paper presents a general overview on most of the material available in the literature on the subject and also comments on the different, and sometimes conflicting solutions presented in various works. Different aspects of the phenomenon are discussed including sinusoidal (lateral) and helical buckling and influence of torque.

ABSTRACT: Theoretical models and experimental data for buried tube buckling are reviewed, and linear buckling solutions based on the elastic continuum model for the ground are selected as being most suitable for the design of buried flexible metal tubes. An examination of both theory and experiment confirms that maximum rather than average hoop thrust should be used to characterize the loads in the buried structure. Various scalar correction factors are recommended for use in calibrating the preferred buckling theory so that it can be used in the design of buried flexible tubes.

ABSTRACT: As technology continues towards smaller, thinner and lighter devices, more stringent demands are placed on thin polymer films as diffusion barriers, dielectric coatings, electronic packaging and so on. Therefore, there is a growing need for testing platforms to rapidly determine the mechanical properties of thin polymer films and coatings. We introduce here an elegant, efficient measurement method that yields the elastic moduli of nanoscale polymer films in a rapid and quantitative manner without the need for expensive equipment or material-specific modelling. The technique exploits a buckling instability that occurs in bilayers consisting of a stiff, thin film coated onto a relatively soft, thick substrate. Using the spacing of these highly periodic wrinkles, we calculate the film’s elastic modulus by applying well-established buckling mechanics. We successfully apply this new measurement platform to several systems displaying a wide range of thicknesses (nanometre to micrometre) and moduli (MPa to GPa).

ABSTRACT: The study of statistical mechanics of thermal fluctuations of graphene—the prototypical two-dimensional material—is rendered rather complicated due to the necessity of accounting for geometric deformation nonlinearity. Unlike fluid membranes such as lipid bilayers, coupling of stretching and flexural modes in solid membranes like graphene leads to a highly anharmonic elastic Hamiltonian. Existing treatments draw heavily on analogies in the high-energy physics literature and are hard to extend or modify in the typical contexts that permeate materials, mechanics and some of the condensed matter physics literature. In this study, using a variational perturbation method, we present a “mechanics-oriented” treatment of the thermal fluctuations of elastic sheets such as graphene and evaluate their effect on the effective bending stiffness at
finite temperatures. In particular, we explore the size, pre-strain and temperature dependency of the out-of-plane fluctuations, and demonstrate how an elastic sheet becomes effectively stiffer at larger sizes. Our derivations provide a transparent approach that can be extended to include multi-field couplings and anisotropy for other 2D materials. To reconcile our analytical results with atomistic considerations, we also perform molecular dynamics simulations on graphene and contrast the obtained results and physical insights with those in the literature.

ABSTRACT: Two buckling modes have been observed in thin films: buckle delamination and wrinkling. This letter identifies the conditions for selecting the favored buckling modes for elastic films on elastic substrates. Transition from one buckling mode to another is predicted as the stiffness ratio between the substrate and the film or is predicted for variation of the stiffness ratio between the substrate and the film or variation of the interfacial defect size. The theoretical results are demonstrated experimentally by observing the coexistence of both buckling modes and mode transition in one film-substrate system.

ABSTRACT: A series of studies have been conducted for mechanical behavior of elastic thin films on compliant substrates. Under tension, the film may fracture by growing channel cracks. The driving force for channel cracking (i.e., the energy release rate) increases significantly for compliant substrates. Moreover, channel cracking may be accompanied by interfacial delamination. For a film on a relatively compliant substrate, a critical interface toughness is predicted, which separates stable and unstable delamination. For a film on a relatively stiff substrate, however, a channel crack grows with no delamination when the interface toughness is greater than a critical value. An effective energy release rate for the steady-state growth of a channel crack is defined to account for the influence of interfacial delamination on both the fracture driving force and the resistance, which can be significantly higher than the energy release rate assuming no delamination. Alternatively, when the film is under compression, it tends to buckle. Two buckling modes have been observed, one with interfacial delamination (i.e., buckle-delamination) and the other without delamination (i.e., wrinkling). By comparing the critical stresses for the onset of buckling, we give a criterion for the
selection of the buckling modes, which depends on the stiffness ratio between the film and the substrate as well as the interface defects. A general conclusion from these studies is that, whether tension or compression, the interfacial properties are critical in controlling the morphology and failure of elastic thin films on compliant substrates.

ABSTRACT: This paper develops a model for evolving wrinkles in a bilayer thin film consisting of an elastic layer and a viscoelastic layer. The elastic layer is subjected to a compressive residual stress and is modeled by the nonlinear von Karman plate theory. A thin layer approximation is developed for the viscoelastic layer. The stability of the bilayer and the evolution of wrinkles are studied first by a linear perturbation analysis and then numerically. Three stages of the wrinkle evolution are identified: initial growth of the fastest growing mode, intermediate growth with mode transition, and, finally, an equilibrium wrinkle state. DOI: 10.1115/1.2043191.

ABSTRACT: The unique lattice structure and properties of graphene have drawn tremendous interests recently. By combining continuum and atomistic approaches, this paper investigates the mechanical properties of single-atom-layer graphene sheets. A theoretical framework of nonlinear continuum mechanics is developed for graphene under both in-plane and bending deformation. Atomistic simulations are carried out to deduce the effective mechanical properties. It is found that graphene becomes highly nonlinear and anisotropic under finite-strain uniaxial stretch, and coupling between stretch and shear occurs except for stretching in the zigzag and armchair directions. The theoretical strength (fracture strain and fracture stress) of perfect graphene lattice also varies with the chiral direction of graphene and properties of graphene have drawn tremendous interests recently. By combining continuum and atomistic approaches, this paper investigates the mechanical properties of single-atom-layer graphene sheets. A theoretical framework of nonlinear continuum mechanics is developed for graphene under both in-plane and bending deformation. Atomistic simulations are carried out to deduce the effective mechanical properties. It is found that graphene becomes highly nonlinear and anisotropic under finite-strain uniaxial stretch, and coupling between stretch and shear occurs except for stretching in the zigzag and armchair directions. The theoretical strength (fracture strain and fracture stress) of perfect graphene lattice also varies with the chiral direction of uniaxial stretch. By rolling graphene sheets into cylindrical tubes of various radii, the bending modulus of graphene is obtained. Buckling of graphene ribbons under uniaxial compression is simulated and the critical strain for the onset of buckling is compared to a linear buckling analysis.

ABSTRACT: This paper presents a bilayer model to account for surface effects on the wrinkling of ultrathin polymer films. Assuming a surface layer of finite thickness, effects of surface properties on the critical strain, the equilibrium wavelength, and the wrinkle amplitude are discussed in comparison with conventional analysis. Experimental measurements of wrinkling in polymer films with thickness ranging from 200 nm to 5 nm are conducted. The bilayer model provides a consistent understanding of the experiments that deviate from conventional analysis for thickness less than 30 nm. A set of empirical surface properties is deduced from the experimental data.

ABSTRACT: The nonlinear mechanical response of monolayer graphene on polyethylene terephthalate (PET) is characterised using in-situ Raman spectroscopy and atomic force microscopy. While interfacial stress transfer leads to tension in graphene as the PET substrate is stretched, retraction of the substrate during unloading imposes compression in the graphene. Two interfacial failure mechanisms, shear sliding under tension and buckling under compression, are identified. Using a nonlinear shear-lag model, the interfacial shear strength is found to range between 0.46 and 0.69 MPa. The critical strain for onset of interfacial sliding is ~0.3%, while the maximum strain that can be transferred to graphene ranges from 1.2% to 1.6% depending on the interfacial shear strength and graphene size. Beyond a critical compressive strain of around ~0.7%, buckling ridges are observed after unloading. The results from this work provide valuable insight and design guidelines for a broad spectrum of applications of graphene and other 2D nanomaterials, such as flexible and stretchable electronics, strain sensing, and nanocomposites.

“Entropic effects of thermal rippling on van der Waals interactions between monolayer graphene and a rigid substrate”, Journal of Applied Physics, November 2015, DOI: 10.1063/1.4941987

ABSTRACT: Graphene monolayer, with extremely low flexural stiffness, displays spontaneous rippling due to
termperature. When a graphene membrane is placed on a solid substrate, the adhesive interactions between graphene and the substrate could considerably suppress thermal rippling. On the other hand, the statistical nature of thermal rippling adds an entropic contribution to the graphene-substrate interactions. In this paper we present a statistical mechanics analysis on thermal rippling of monolayer graphene supported on a rigid substrate, assuming a generic form of van der Waals interactions between graphene and substrate at T = 0 K. The rippling amplitude, the equilibrium average separation, and the average interaction energy are predicted simultaneously and compared with molecular dynamics (MD) simulations. While the amplitude of thermal rippling is reduced by adhesive interactions, the entropic contribution leads to an effective repulsion. As a result, the equilibrium average separation increases and the effective adhesion energy decreases with increasing temperature. Moreover, the effect of a biaxial pre-strain in graphene is considered, and a buckling instability is predicted at a critical compressive strain that depends on both the temperature and the adhesive interactions. Limited by the harmonic approximations, the theoretical predictions agree with MD simulations only for relatively small rippling amplitudes but can be extended to account for the anharmonic

effects.

Subject to a compressive membrane force, a solid film on a liquid layer may form wrinkles. The three-dimensional analysis, which accounts for substrate bending and interfacial forces, is performed using analytic and numerical methods. We show that the wrinkling of thin films is a collective phenomenon, and that it is controlled by a dimensionless number called the ‘wrinkling length’. The wrinkling length is inversely proportional to the square root of the film thickness, and it determines the wavelength of the wrinkles. The analytical theory is confirmed by atomistic simulations, and by experiments on thin films of different materials. The wrinkling instability is similar to the buckling of a column under compressive force. However, the wrinkling length of thin films is much smaller than the radius of curvature of the substrate. This suggests that the wrinkling of thin films is a unique phenomenon that is not observed in the buckling of columns.

ABSTRACT: A compressively strained elastic film bonded to a viscous layer can form wrinkles. The present study provides a theoretical model for the wrinkling process. The elastic film is modeled with the nonlinear theory of a thin plate subject to in-plane and out-of-plane loads. The flow of the viscous layer is modeled with the theory of lubrication. The interface between the elastic film and the viscous layer is assumed to be perfect with no slipping or debonding. A set of partial differential equations evolves the deflection and the in-plane displacements as functions of time. A linear stability analysis identifies the critical wave number, below which the elastic film is unstable and the wrinkles can grow. For any fixed wave number less than the critical wave number, the wrinkles reach a kinetically constrained equilibrium configuration, in which the stress is partially relaxed in the elastic film and the viscous layer stops flowing. Numerical simulations reveal rich dynamics of the system with many unstable equilibrium configurations.

ABSTRACT: Since the first successful synthesis of graphene just over a decade ago, a variety of two-dimensional (2D) materials (e.g., transition metal-dichalcogenides, hexagonal boron-nitride, etc.) have been discovered. Among the many unique and attractive properties of 2D materials, mechanical properties play important roles in manufacturing, integration and performance for their potential applications. Mechanics is indispensable in the study of mechanical properties, both experimentally and theoretically. The coupling between the mechanical and other physical properties (thermal, electronic, optical) is also of great interest in exploring novel applications, where mechanics has to be combined with condensed matter physics to establish a scalable theoretical framework. Moreover, mechanical interactions between 2D materials and various substrate materials are essential for integrated device applications of 2D materials, for which the mechanics of interfaces (adhesion and friction) has to be developed for the 2D materials. Here we review recent theoretical and experimental works related to mechanics and mechanical properties of 2D materials. While graphene is the most studied 2D material to date, we expect continual growth of interest in the mechanics of other 2D materials beyond graphene.

ABSTRACT: Swell-induced surface instability has been observed experimentally in rubbers and gels. Here we present a theoretical model that predicts the critical condition along with a characteristic wavelength for swell-induced surface instability in substrate-confined hydrogel layers. The effect of surface tension is found to be critical in suppressing short-wavelength modes of instability, while the substrate confinement suppresses long-wavelength modes. Together, an intermediate wavelength is selected at a critical swelling ratio for the onset of surface instability. Both the critical swelling ratio and the characteristic wavelength depend on the initial thickness of the hydrogel layer as well as other material properties of the hydrogel. It is found that the hydrogel layer becomes increasingly stable as the initial layer thickness decreases. A critical thickness is predicted, below which the hydrogel layer swells homogeneously and remains stable at the equilibrium state.

ABSTRACT: This paper develops a theoretical model for wrinkling of an elastic film on a viscoelastic layer. The film is elastic and subjected to a compressive residual strain. The viscoelastic layer is sandwiched between the film and a rigid substrate. The nonlinear von Karman plate theory is employed to model the film, and a thin-layer approximation is adopted for the viscoelastic layer. The stability of the system and the kinetics of structural evolution are studied first by a linear perturbation analysis and then by numerical simulations, both for plane strain deformation only. Three stages of evolution are identified: initial growth of the fastest growing mode, intermediate growth with mode transition, and finally an equilibrium wrinkled state. The results qualitatively agree with experimental observations of wrinkling in metal/polymer bilayer films.

Rui Huang (Department of Aerospace Engineering and Engineering Mechanics, University of Texas at Austin, TX, USA), “A Kinetics Approach to Surface Wrinkling of Elastic Thin Films”, No publisher or date given in the pdf file; the most recent reference is dated 2011

ABSTRACT: Complex wrinkle patterns have been observed in various thin film systems, typically with integrated hard and soft materials for various applications as well as in nature. The underlying mechanism of wrinkling has been generally understood as a stress-driven instability. On an elastic substrate, equilibrium and energetics set the critical condition and select the wrinkle wavelength and amplitude. On a viscous substrate, wrinkles grow over time and kinetics select the fastest growing mode. Moreover, on a viscoelastic substrate, both energetics and kinetics play important roles in determining the critical condition, the growth rate, and wrinkle patterns. The dynamics of wrinkling, while analogous to other phase ordering phenomena, is rich and distinct under the effects of stress and film-substrate interactions. In this chapter, a kinetics approach is presented for wrinkling of isotropic and anisotropic elastic films on viscoelastic substrates. Analytic solutions are obtained by a linear perturbation analysis and a nonlinear energy minimization method, which predict the kinetics of wrinkle growth at the early stage and the equilibrium states at the long-time limit, respectively. In between, a power-law coarsening of the wrinkle wavelength is predicted by a scaling analysis. Furthermore, the kinetics approach enables numerical simulations that demonstrate emergence and transition of diverse wrinkle patterns (ordered and disordered) under various conditions.

Thin films bonded to compliant substrates often develop wrinkles when subjected to an applied or inherent compressive stress. This paper presents a bilayer model to account for surface effects on the wrinkling of ultrathin solid films. Assuming a surface layer of finite thickness, effects of surface properties on the critical strain, the equilibrium wavelength, and the wrinkle amplitude are discussed in comparison with conventional analysis. We apply this model to explain experimental observations of wrinkling in thin polymer films. The measured wrinkle wavelengths and amplitudes deviate from conventional analysis for ultrathin films with thickness less than 30 nm. The bilayer model provides a consistent understanding of the observed deviations, based on which a set of material properties for the surface and the bulk of the polymer films are deduced from the experimental data.
analyses show a significant shear compressive strain lower than previous solutions for both wrinkling and buckle eigenvalue analysis. For an intermediate delamination size, a missing delamination crack, the critical strain for the onset of buckling instability is predicted by finite element normal traction at the interface and interfacial force. In comparison with a nonlinear finite element analysis, an approximate formula is derived to estimate the interfacial force.

Recent experiments have observed that concomitant wrinkling and buckle instability. Two commonly observed buckling modes, buckle and delamination, exist and co-evolve. In this paper, by analytical and finite element methods, we present a study on concomitant wrinkling and delamination. Post-buckling analyses show a significant shear-lag effect with an effective load transfer length three orders of magnitude.

Landis and Rui Huang (Department of Aerospace Engineering and Engineering Mechanics, University of Texas, Austin, TX 78712, USA), “Concomitant wrinkling and buckle-delamination of elastic thin films on compliant substrates,” Mechanics of Materials Vol. 43, No. 11, pp 627-642, November 2011, https://doi.org/10.1016/j.mechmat.2011.08.003

ABSTRACT: Compressing a thin elastic film attached to a thick compliant substrate can lead to buckling instability. Two commonly observed buckling modes, buckle-delamination and wrinkling, have each been analyzed separately in previous studies. Recent experiments have observed that the two modes can co-exist and co-evolve. In this paper, by analytical and finite element methods, we present a study on concomitant wrinkling and buckle-delamination for an elastic film on a highly compliant substrate. First, without delamination, we present an analytical solution for wrinkling that takes into account the effect of Poisson’s ratio of the substrate. In comparison with a nonlinear finite element analysis, an approximate formula is derived to estimate the normal traction at the interface and to predict initiation of wrinkle-induced delamination. Next, with a pre-existing delamination crack, the critical strain for the onset of buckling instability is predicted by finite element eigenvalue analysis. For an intermediate delamination size, a mixed buckling mode is predicted with the critical compressive strain lower than previous solutions for both wrinkling and buckle-delamination. Post-buckling analyses show a significant shear-lag effect with an effective load transfer length three orders of magnitude.
greater than the film thickness. Finally, concomitant wrinkling and buckle-delamination is simulated to illustrate the interaction between the two buckling modes, and the results are discussed in view of failure mechanisms and applications in thin film metrology.

ABSTRACT: Distributed actuators offer spatially distributed actuations and they are usually effective to multiple modes of a continuum. Spatially filtered distributed vibration controls of a laminated cylindrical shell and a piezoelectric shell are investigated, and their control effectivenesses are evaluated in this study. In general, there are two control actions, the in-plane membrane control forces and the counteracting control moments, induced by the distributed actuator in the laminated shell. There is only an in-plane circumferential control force in the piezoelectric shell. Analyses suggest that in either case the control actions are effective in odd natural modes and ineffective in even modes. Spatially filtered control effectiveness and active damping of both shells are studied.

ABSTRACT: Shallow paraboloidal shells of revolution are common components for reflectors, mirrors, etc. This study is to investigate the micro-control actions and distributed control effectiveness of precision
paraboloidal shell structures laminated with segmented actuator patches. Mathematical models and governing equations of the paraboloidal shells laminated with distributed actuator layers segmented into patches are presented first, followed by formulations of distributed control forces and micro-control actions including meridional/circumferential membrane and bending control components based on an assumed mode shape function and the Taylor series expansion. Distributed control forces, patch sizes, actuator locations, micro-control actions, and normalized control authorities of a shallow paraboloidal shell are then analyzed in a case study. Analysis indicates that 1) the control forces, and membrane/bending components are mode and location dependent, 2) the meridional/circumferential membrane control actions dominate the overall control effect, 3) there are optimal actuator locations resulting in the maximal control effects at the minimal control cost for each natural mode. The analytical results provide generic design guidelines for actuator placement on precision shallow paraboloidal shell structures.

ABSTRACT: Adaptive structures with controllable geometries and shapes are rather useful in many engineering applications, such as adaptive wings, variable focus mirrors, adaptive machines, micro-electromechanical systems, etc. Dynamics and feedback control effectiveness of adaptive shells whose curvatures are actively controlled and continuously changed are evaluated. An adaptive piezoelectric laminated cylindrical shell composite with continuous curvature changes is studied, and its natural frequencies and controlled damping ratios are evaluated. The curvature change of the adaptive shell starts from an open shallow shell (300) and ends with a deep cylindrical shell (360°). Dynamic characteristics and control effectiveness (via the proportional velocity feedback) of this series of shells are investigated and compared at every 30° curvature change. Analytical solutions suggest that the lower modes are sensitive to curvature changes and the higher modes are relatively insensitive.

Horn-Sen Tzou, Mike S. Lih and Gregory Hickey, “Distributed modal signal of thin paraboloidal shells”, Submitted to Internation Union of Theoretical and Applied Mechanics, IUTAM2000, Symposium on Smart Structures and Structural Systems, Magdeburg, Germany, September 26-29, 2000

ABSTRACT: Flexible paraboloidal shell of revolution is considered one of the most difficult geometry among all shell and non-shell structures, such as spherical shells, cylindrical shells, conical shells, plates, rings, beams, etc. Often space structures and civil structures are designed based on the paraboloidal shell, because of its functionality, beauty, and strength. Static and dynamic vibration analyses of these paraboloidal shells have been investigated analytically, numerically or experimentally over the years. However, due to its complexity, analytical solutions and experimental data are still scarce and only limited to simple boundary conditions. Thus, numerical (finite element) technique becomes popular and useful in engineering design and applications. This paper is to present (analytical) assumed solution technique and to evaluate distributed sensing characteristics - modal voltages - of paraboloidal shells laminated with distributed piezoelectric layers.

ABSTRACT: Optical membrane mirrors are promising key components for future space telescopes. Due to their ultra-thin and high flexible properties, the surfaces of these membrane mirrors are susceptible to temperature variations. Therefore adaptive shape control of the mirror is essential to maintain the surface precision and to ensure its working performance. However, researches on modeling and control of membrane mirrors under thermal loads are sparse in open literatures. A 0.2 m diameter scale model of a polyimide membrane mirror is developed in this study. Three Polyvinylidene fluoride (PVDF) patches are laminated on the non-reflective side of the membrane mirror to serve as in-plane actuators. A new mathematical model of the piezoelectric actuated membrane mirror in multiple fields, (i.e., thermal, mechanical, and electrical field) is established, with which dynamic and static behaviors of the mirror can be analyzed. A closed-loop membrane mirror shape control system is set up and a surface shape control method based on an influence function matrix of the mirror is then investigated. Several experiments including surface displacement tracking and thermal deformation alleviation are performed. The deviations range from 15 μm to 20 μm are eliminated within 0.1 s and the residual deformation is controlled to micron level, which demonstrates the effectiveness of the proposed membrane shape control strategy and shows a satisfactory real-time performance. The proposed research provides a technological support and instruction for shape control of optical membrane mirrors.

ABSTRACT: In this study, a thin cylindrical shell is actively controlled by photostrictive patches which can produce photodeformation strains under the illumination of ultraviolet lights. Governing equations of the cylindrical shell laminated with the photostrictive actuators oriented in the circumferential direction are established. With the uniform illumination and the alternate illumination schemes, the bending control effect and the membrane control effect of the new actuator configuration are analyzed and evaluated with respect to the curvature angles of the cylindrical shell. Considering the multi-field coupling behavior of the photo-strictive actuators, two types of control algorithms with constant light intensity and variable light intensity are adopted. Using the two control algorithms, time histories of the transverse displacement, control light intensity, photo-induced electric field, temperature, and control force are presented. The results of time history analysis show that the constant light intensity control provides better control performance as compared with the variable light intensity control. Based on the configuration of two paired actuators, both the uniform illumination and the
alternate illumination schemes are analyzed and compared. The alternate illumination scheme improves the modal control effects to some modes which are decided by the actuator configuration and the mode shapes of the cylindrical shell.

ABSTRACT: Parabolic cylindrical shell panel is useful in the aerospace. Light-activated shape memory polymer is a novel kind of smart materials. It is capable of offering a non-contact control way at the room temperature. In this study, the parabolic cylindrical shell panel laminated with light-activated shape memory polymer actuators is analyzed. First, the dynamic equations of the parabolic cylindrical shell panel coupled with light-activated shape memory polymer actuators are established; the modal control force of light-activated shape memory polymer actuators is derived with the modal expansion method. Then, the strain variation of light-activated shape memory polymer actuators is modeled based on the chemical kinetics. Furthermore, Young’s modulus of light-activated shape memory polymer actuators is measured through the biaxial tension experiments. The strain variation of light-activated shape memory polymer actuator with initial strain is also measured. The established strain model is validated by the experimental data of strain variation. In this case study, the snap-back control effects of the first four modes, that is, the (1,3), (1,4), (2,4), and (2,5) modes are evaluated. The study shows light-activated shape memory polymer actuators are effective to control the vibration of parabolic cylindrical shell panels. Light-activated shape memory polymer actuators have potential applications for the vibration control of double-curvature shells.

ABSTRACT: The converse flexoelectric effect, i.e., the polarization (or electric field) gradient-induced internal stress (or strain), can be utilized to actuate and control flexible structures. This study focuses on the microscopic actuation behavior and effectiveness of a flexoelectric actuator patch laminated on an elastic ring shell. An atomic force microscope (AFM) probe is placed on the upper surface of the flexoelectric patch to induce an inhomogeneous electric field resulting in internal stresses of the actuator patch. The flexoelectric stress-induced membrane control force and bending control moment regulate the ring vibration and their actuation mechanics, i.e., transverse and circumferential control actions, are, respectively, studied. For the transverse direction, the electric field gradient quickly decays along the ring thickness, resulting in a nonuniform transverse distribution of the induced stress, and this distribution profile is not influenced by the actuator thickness. The flexoelectric-induced circumferential membrane control force and bending control moment resemble the Dirac delta functions at the AFM contact point. The flexo-electric actuation can be regarded as a localized drastic bending to the ring. To evaluate the actuation effect, dynamic responses and controllable displacements of the elastic ring with flexoelectric actuations are analyzed with respect to design parameters, such as the flexoelectric patch thickness, AFM probe radius, ring thickness, and ring radius.

ABSTRACT: An open parabolic cylindrical shell panel plays a key role in radial signal collection, reflection, and/or transmission applied to radar antennas, space reflectors, solar collectors, etc. Active vibration control can suppress unexpected fluctuation and maintain its precision surface and operations. This study aims to investigate the distributed active actuation behavior of adaptive open parabolic cylindrical shell panels using piezoelectric actuator patches. Dynamic equations of parabolic cylindrical shells laminated with piezoelectric actuator patches are presented first. Then, the actuator induced modal control force is defined based on a newly derived mode shape function. As the actuator area varies due to the curvature change, the normalized actuation effectiveness (i.e., modal control force per unit actuator area) is further evaluated. When the actuator area shrinks to infinitesimal, the expression of microscopic local modal control force is obtained. The total control force and its three components exhibit distinct characteristics with respect to shell geometries, modes, and actuator properties. Analyses suggest that the control force contributed by the membrane force component dominates the total actuation effect. The bending-contributed component increases with the corresponding mode number, while the membrane-contributed component decreases. Actuation effectiveness of two shell geometries, from shallow to deep, and actuator sizes are evaluated. Analysis of optimal actuator locations reveals that actuators placed at the maximal shell curvature are more effective and maximize the control effects.

Thus, the flexoelectric effect could provide an effective alternative for structural sensing. Vibrations. For a flexible structure, the flexoelectric signal is much more prominent than the piezoelectric one for sensing of bending vibrations. Sensing capabilities of these two materials and mechanisms are compared with respect to ring thickness, sensor thickness, and ring radius in case studies. Results show that the piezoelectric sensing signal appears to be sensitive for both bending-dominant and membrane-dominant vibrations, while the flexoelectric signal is much more prominent than the piezoelectric one for sensing of bending-dominant vibrations. For a flexible structure performing transverse vibration, the bending behavior is usually dominant. Thus, the flexoelectric effect could provide an effective alternative for structural sensing.

ABSTRACT: Piezoelectric materials have been widely used for structural sensing due to the linear electromechanical coupling effect. Flexoelectricity, generally existing in all dielectrics, describes the linear inhomogeneous electromechanical coupling phenomena. Previous studies have shown that the direct flexoelectric effect is sensitive to the bending deformation. This study focuses on comparison and differences between two sensing mechanisms, that is, the flexoelectric and the piezoelectric effects, and explores their distinctive characteristics and potential applications. Based on the direct flexoelectric/ piezoelectric effects, flexoelectric/piezoelectric materials treated as flexoelectric/piezoelectric sensors are applied to two ring models with identical dimensions. The mathematical models of thin elastic rings laminated with flexoelectric/piezoelectric sensors are established. Open-circuit sensing signals are derived for further evaluation and comparison. Sensing capabilities of these two materials and mechanisms are compared with respect to ring thickness, sensor thickness, and ring radius in case studies. Results show that the piezoelectric sensing signal appears to be sensitive for both bending-dominant and membrane-dominant vibrations, while the flexoelectric signal is much more prominent than the piezoelectric one for sensing of bending-dominant vibrations. For a flexible structure performing transverse vibration, the bending behavior is usually dominant. Thus, the flexoelectric effect could provide an effective alternative for structural sensing.

ABSTRACT: In this paper, free and forced vibration of simply-supported Single-walled carbon nanotube is investigated under the moving nanoparticle by considering nonlocal cylindrical shell model. To validate the theoretical results, modal analysis of nanotube is conducted using ANSYS commercial software. Excellent agreement is exhibited between the results of two different methods. Furthermore, the dynamic response of SWCNT under moving nanoparticle is also studied. It is assumed that the nanoparticle travels along the center of nanotube with constant velocity and the van der Waals force between CNT and particle is taken into account. The dynamic response of the SWCNT under the influence of C60 particle obtained using dynamic Green’s function and modal expansion. The obtained results show that the nonlocal scale effect decreases the natural frequency and dynamic displacement of the CNT.

ABSTRACT: In order to study the free vibration of simply supported circular cylindrical shells, a semi-analytical procedure is discussed in detail. In this technique, beam function is used as an approximation for simply supported boundary conditions. A literature review reveals that beam functions are used extensively in predicting natural frequencies of shells. Since this method does not involve with boundary condition equations, there is no need to deal with intense calculations. Hence, it is important to check the accuracy of this approximate technique. So this method was applied to ten different shell theories: 1) Donnell-Mushtari, 2) Love-Timoshenko, 3) Arnold-Warburton, 4) Houghton-Johns, 5) Flugge-Byrne-Lur’ye, 6) Reissner-Naghd-Berry, 7) Sanders, 8) Vlasov, 9) Kennard-Simplified and 10) Soedel. The approximate procedure was compared favorably with experimental results. Finally, variations and influences of length, radius and thickness were studied on amplitude ratios.

ABSTRACT: The general equation for transverse vibration of double-viscoelastic-FGM-nanoplate system with viscoelastic Pasternak medium in between and each nanoplate subjected to in-plane edge loads is formulated on the basis of the Eringen's nonlocal elastic theory and the Kelvin model. The factors of the structural damping, medium damping, small size effect, loading ratio, and Winkler modulus and shear modulus of the medium are incorporated in the formulation. Based on the Navier's method, the analytical solutions for vibrational frequency and buckling load of the system with simply supported boundary conditions are obtained. The influences of these factors on vibrational frequency and buckling load of the system are discussed. It is demonstrated that the vibrational frequency of the system for the out-of-phase vibration is dependent upon the structural damping, small size effect and viscoelastic Pasternak medium, whereas the vibrational frequency for the in-phase vibration is independent of the viscoelastic Pasternak medium. While the buckling load of the system for the in-phase buckling case has nothing to do with the viscoelastic Pasternak medium, the buckling load for the out-of-phase case is related to the small size effect, loading ratio and Pasternak medium.

ABSTRACT: In this paper, the effect of humidity conditions on thermal buckling analysis of graphene system contained two layers under different boundary conditions is investigated. The two-variable shear deformation plate theory is employed with the nonlocal continuum theory to deduce the governing stability equations. These equations are solved analytically to obtain the thermal buckling of the nanoplate system with simply supported, clamped and free boundary conditions. The present system of double-layered graphene sheets is composed from two sheets of graphene joined together by an elastic medium and hedged by two-parameter foundations. The external foundations are modeled as Winkler–Pasternak model. Two characteristic types of thermal buckling are considered: synchronous and asynchronous modes of buckling. The temperature rise and moisture concentration are assumed as a fixed, linear or nonlinear function of $z$ (along the thickness direction). For the validation of the formulations, the present results are compared with those published in the references. Furthermore, the influences of the nonlocal parameter, humidity and other parameters on thermal buckling of double-layered graphene system are all discussed.

ABSTRACT: The free vibration analysis of symmetrically laminated composite circular plates with curvilinear fibers is performed using the first-order shear deformation theory along with a curved hierarchical square finite element. The blending function method is used to describe accurately the geometry of the circular plate. The hierarchical shape functions are constructed from Legendre orthogonal polynomials. The element stiffness and mass matrices are integrated numerically by means of the Gauss-Legendre quadrature. The equations of motion are derived using Lagrange's method. Results for the fundamental frequency are obtained for clamped and soft simply supported laminated composite circular plates with E-glass, graphite, and boron curvilinear fibers in epoxy matrices. The element is validated by means of the convergence test and comparison with published data for isotropic and laminated composite circular plates with rectilinear fibers. Contour plots of frequency as a function of fiber orientation angles for laminated composite circular plates with curvilinear fibers are presented. The fiber material and boundary conditions are shown to influence the distribution of frequency throughout the design space. Frequency curves as a function of fiber orientation angles for the first five modes of laminated composite circular plates with curvilinear fibers are also presented. They reveal that none of the first five modes of clamped and soft simply supported laminates is affected by crossing but modes 3 and 4 of clamped graphite/epoxy and boron/epoxy laminates are affected by veering.

ABSTRACT: A skew $p$-element is developed for the nonlinear free vibration of variable stiffness symmetric skew laminates. The governing equations are based on thin plate theory and Von Karman strains. The fundamental frequencies and normal modes are computed for fully clamped edge conditions. The equations of motion are derived using Lagrange's method. By employing the harmonic balance method, the transformation from time to frequency domain is facilitated. The nonlinear equations are solved using the iterative technique known as the linearized updated mode method. The numerical results are validated with the help of convergence tests and comparisons with published data. New results are presented for variable stiffness symmetric skew laminates with different fiber configurations showing the effects of variation in skew angle on frequency, normal mode, and degree of hardening.

ABSTRACT: This paper introduces a model for strengthening slender reinforced concrete columns. The proposed technique aims at controlling second order lateral deflections using longitudinal high-modulus bonded reinforcement, thereby altering the loading path to intercept the axial load-moment (P-M) interaction curve at a higher axial capacity. With the availability of high- and ultra-high-modulus carbon fiber reinforced polymer (CFRP) plates, this approach should be quite efficient according to Euler’s buckling rule, in which, column strength is stiffness-controlled. This approach is different from the classical transverse wrapping method for confinement; a technique that achieves strengthening by enlarging the (P-M) diagram in the compression-
controlled region. The proposed model accounts for concrete nonlinearity in compression, cracking in tension, steel rebar plasticity, and certainly geometric nonlinearity, in addition to the possibility of premature CFRP debonding failure in tension and the lower CFRP strength in compression than tension. The model is validated against experimental results and used in a parametric study to assess the effects of slenderness ratio $\lambda$, axial load initial eccentricity ratio $e_0/h$, and CFRP reinforcement ratio $\zeta_f$, and modulus $E_f$. It was shown that strength gain increases from 17 to 30% as $\lambda$ increases from 20 to 120, when a very small $\zeta_f$ of 0.5% is used. A range of 0.1 to 1% for $\zeta_f$ results in a 4 to 41% strength gain, while a range of 100 to 500 GPa for $E_f$ results in a 5 to 26% gain. As $e_0/h$ increases from 0.05 to 0.6, the gain increases from 17 to 90%.

M.R. Bambach (Dept. of Civil Engineering, Monash University, Australia), “Unified element and section approach to design of cold-formed steel structures”, ASCE Journal of Structural Engineering, Vol. 136, No. 4, April 2010

ABSTRACT: Slender open-section cold-formed steel members that contain flanges with edge stiffeners may buckle in different modes and with mode interactions. The element design approach (effective width method) has been shown to produce unconservative capacity predictions for a particular class of such members. This paper presents a modification to the effective width method derived from an investigation of the fundamental behavior of edge stiffened flange elements and sections that contain them. The modified element design approach is validated against the results of 913 compression and bending members collected from the literature, where all section and member buckling modes and interactions were evident. A section design approach is also presented which is directly in line with the element approach. The unified element and section approach is shown to provide accurate and reliable design solutions for cold-formed steel compression and flexural members. Proposals for the North American specification for cold-formed steel structures are presented.

ABSTRACT: This chapter summarises recent research on the strengthening of thin-walled steel structures with fibre-reinforced polymers. The focus is on steel square hollow sections strengthened with carbon fibre-reinforced polymer. An extensive series of experiments with a wide range of thin-walled steel section geometries where the exterior surfaces of the tube walls were strengthened with bonded carbon fibres, is discussed. Experiments were performed under quasi-static axial compression to investigate strengthening with regards to elastic buckling and compression strength, and under axial impact to investigate strengthening with regards to dynamic axial crushing and associated crushworthiness indicators. Design models are developed and compared with the experimental results, and optimisation is discussed.

M. Reza Eslami (Mechanical Engineering Department, Amirkabir University of Technology, Tehran, Iran), “Buckling of Spherical Shells”, a chapter in Buckling and Postbuckling of Beams, Plates, and Shells by M. Reza Eslami, Springer, 2018, pp 465-537

ABSTRACT: Spherical shells, as part of structural systems, are frequently used in many structural design problems. This type of shells is capable to stand high internal or external pressures and is especially quite stable under external pressures. The behavior of deep spherical shells, in particular, under external pressure is quite unique and the bifurcation load is far from expectation. Ancient spherical domes with wide spans in historic buildings is a good example of such structure to show its remarkable stability feature. Spherical shells used in the industrial applications are exposed to different types of mechanical or thermal loads. Under these circumstances, it is necessary to predict the critical mechanical and/or thermal buckling loads of spherical shells. Closed form solutions for the buckling loads are valuable tools for designer in the design stage. This chapter presents the methods to calculate critical buckling temperatures or pressures in spherical shell made of isotropic and functionally graded materials for both perfect and imperfect shells.

ABSTRACT: Structural stability is one, or the most design driving criterion for aerospace structures. The accurate prediction of the various forms of buckling becomes especially important when seeking a minimum weight design. The grid-stiffened structures, with the isogrid and orthogrid being the most popular forms, provide a large design space to investigate, but also exhibit a complex behaviour in terms of structural stability. This paper focuses on buckling of the panel as a whole by presenting and comparing semi-analytical methods for global and panel buckling, where the latter takes the discrete nature of the stiffening structure into account. Results are presented for parameter studies of the composite cylindrical grid-stiffened shell including mechanical effects from panel curvature, stiffener eccentricity, and material orthotropy. The results show panel buckling to occur at significantly lower loads compared to global buckling, with a magnitude depending on the very specific geometry and kind of applied loads.

ABSTRACT: Optimal design of stiffened laminated composite cylinder of symmetric and balanced layup with isogrid form stiffeners is investigated and presented. The isogrid stiffened cylinder is subjected to uniform compressive load. In the optimization for the maximum buckling load, the panel skin laminate stacking sequence and stiffener configuration are chosen as design variables. A smeared model is employed in the buckling analysis of the stiffened composite cylinder. A new variant of particle swarm intelligence algorithm, using multiple swarms, built with quantum and dynamically reconfigurable features is developed and employed in the present investigations. The optimization is carried out using the proposed multi swarm based quantum particle swarm optimisation (PSO) algorithm, taking into consideration of the ply contiguous constraint. An optimal layup of the skin and stiffener configuration has also been obtained by using the proposed dynamic quantum PSO algorithm. Comparisons have been made with quantum PSO, cooperative quantum PSO, multi swarm based hybrid PSO, the newly developed multi swarm versions of quantum PSO and cooperative quantum PSO algorithms. Studies clearly indicate that multi swarm version of quantum PSO algorithms are more consistent and also reliable in providing optimal solutions. The methods presented in this paper will be applicable in general to the design of laminate composite structures.

ABSTRACT: The buckling problem of stiffened plate panels under longitudinal compression is studied. The fundamental and practical aspects of the artificial neural networks are demonstrated and a view of their structures, topology and strengths is presented. The application of the neural network to the problem of buckling and ultimate strength of stiffened plates is explored. Two-hidden layer backpropagation neural network has been used to predict the crossover, local and overall buckling behaviour of the stiffened plates. The effects of the parameters, such as the number of nodes in the input layer, output layer and hidden layer, the pre-process (normalization) of the training patterns, the weight-factors initialization and the selection of the learning rate and momentum coefficient, on the behaviour of the neural network have been investigated. Both the gradient descent (GD) backpropagation algorithm and the conjugate gradient (CG) algorithm have been used and the latter is found to improve the performance (small Mean Square Error) of the neural network model. After training, the generalization of the neural network was tested by the patterns not included in the training patterns. Two structures of networks are worked out as follow:a) The configuration 5:22:13:3 is used to predict the crossover, local and overall buckling stresses of stiffened plates under uniaxial compression.b) The configuration 5:22:13:1 is used to predict the ultimate strength of stiffened plates. Also the shear buckling stress of plate girder is predicted using the same configuration. The neural network model was trained based on experimental results of other researches. The developed neural network is applied to investigate the behaviour of plate girders. The shear buckling stresses are assessed. It is found that normalizing the input and target values of training patterns using zero-mean normalization method reduces the training time. Gaussian weight-factor distribution with range (±1) is found to give a minimum mean square error (MSE) in comparison with other ranges. In addition, the effective values for learning rate and momentum coefficient are (0.3) and (0.6) respectively, and the configuration (22:13) for hidden layer is proved to be very efficient. Plates stiffened by T-type stiffeners are found to have higher values (20% and 25%) of buckling and ultimate strengths in comparison with those having flat and angle types stiffeners. The values of shear buckling stresses of plate girder which predicted by neural network model are greater than the values permitted by the Indian code.

ABSTRACT: Optimization catches application in every field of engineering and science. The procedure of optimization is based on selection of best solution from a group of probable candidates such that the selected response is superior to the others in certain characteristics. Design optimization follows the procedure whereby nominated set of input design variables is automatically modified through an algorithm to acquire outputs that are more desired. High-speed computers, clusters, and workstations reduces human efforts to solve the high fidelity models. The optimization procedure of methodical and concurrent gathering of preferred functions is known as ‘Multi-Objective Optimization (MDO) or Vector Optimization’. This paper discusses different proposed optimization techniques for the buckling of Iso-grid structures from 2005 to 2012. These structures may be fabricated out of simple metals or composites. An Iso-grid panel is a face sheet or a plate with integral stiffening ribs of triangular shape and the structure acts like an isotropic material.

ABSTRACT: A summary of a NASA design analysis and test program on the buckling of large-scale, integrally-stiffened metallic cylinders is presented. The test article designs were developed based on proposed NASA launch vehicle cylinder designs and span a significant portion of the design space. Various loading conditions were applied to the cylinders and include different combinations of axial compression, bending, and internal pressure loads that simulate typical launch vehicle loading scenarios. The data gathered from this test program is being used to develop and validate new analysis-based knockdown factors and design guidelines for these stiffened metallic cylinders. In this paper, the test article designs and fabrication methods are described along with the test facilities and instrumentation. Selected test and finite element analysis results are presented and compared and are used to illustrate the typical response characteristics of the stiffened metallic cylinders considered. Overall, good qualitative agreement is found, however, several discrepancies in the results were
identified across several of the tests. The discrepancies were investigated thoroughly and can be attributed to variations in the as-built skin and stiffener geometry, variations in the measured geometric imperfection, and modeling assumptions associated with the boundary conditions, and loading imperfections. Based on these findings, several refinements were made to the finite element models which significantly improved the correlation between the test and analysis results. These modeling refinements are described and the updated analysis results are presented.

ABSTRACT: Grid-stiffened composite structures, where the skin is stiffened by a lattice of stiffeners, not only allow for significant reduction in structural weight but are also competitive in terms of structural stability and damage tolerance compared with sandwich composite structures. As the development of Automated Fiber Placement (AFP) technology matures, integrated construction of skin and stiffeners is easily manufacturable. Optimization of grid-stiffened structures is needed to fully take advantage of the expanded design possibilities. In this paper, a steering/curved stiffener layout is optimized for grid-stiffened composite structures in order to enhance the structural buckling resistance. A homogenization method is used to calculate the equivalent material properties. Global and local buckling loads are determined by a global/local coupled strategy. A linear variation of stiffener angles is assumed resulting in the formation of a locally rhombic lattice pattern by the stiffeners. Moreover, manufacturing constraints are considered in the optimization by setting a lower bound on the stiffener spacing. Since the calculation is implemented on an equivalent model with a fixed mesh, it is possible to use a gradient-based optimization algorithm. A comparison between the performance of grid-stiffened composite structures with curved stiffeners, with straight stiffeners, and with variable-stiffness skins with curved fibers, reveals the potential of curved stiffener configurations in improving structural efficiency.

An aircraft is a light weight air breathing semi-monocoque complex aerostructure comprising of longerons, bulkheads, stiffeners, stringers, legs, bolts and joints, ribs and other special forms of structures. In its service, it has to sustain mainly aerodynamic, structural, propulsive, fatigue and impact loads. Even though the load carrying agents are the stiffening materials, the loads are firstly faced by the aircraft skin in the form of
shear loads and later on transferred to the stiffening structures inside. These loads give rise to bending, buckling, shear, torsion and warping effects in different magnitudes on the semi-mococque structures. The implementation of the stiffened panel structure can be found inside the fuselage, wings and horizontal and vertical stabilizers of an aircraft. While in operation, an aircraft must resist all the loads said above in all kinds of mission profiles, that is from passenger, cargo, military, reconnaissance to combat situations with varying load spectrum. So it becomes very important and necessary to analyse an aircraft stiffened panel structure subjected to assumed static structural loads and dynamic (modal) loads.

Composite Steel Plate Shear Wall (CSPSW), which is used as the lateral resisting system in tall buildings.

ABSTRACT: Isogrid stiffened structures with a higher specific strength and stiffness due to their lightweight properties are composed of thin outer skin and repetitive equilateral triangular grid stiffeners. These grid stiffeners become isotropic in the plane of the structure and metallic isogrid stiffened structures are still used in an aerospace field such as launch vehicle payload fairings, inter stage adapter rings and fuel tanks. In order to produce these structures, a most of thick metal plate becomes cutoffs while remaining panel with stiffeners and both ends of the panel are welded to each other. This process needs long lead time and a high cost. Therefore we developed an integral molding method of CFRP isogrid cylindrical shells by using a filament winding apparatus [1] and a silicon rubber mold [2] (see Figs. 1 and 2) and performed the uniaxial compression test for the CFRP isogrid cylindrical shells. In this paper, the reinforcement effect of isogrid stiffeners on the compressive strength of CFRP cylindrical shell are shown in Table 1. Maximum compressive loads of CFRP isogrid shell are larger than the total loads of the CFRP shell without the isogrid and the isogrid shell alone. Next, formulations of linear and nonlinear analyses for CFRP isogrid cylindrical shells by using FEM code of ANSYS are presented and the uniaxial compression test of CFRP isogrid cylindrical shells are also shown. After the results of linear and nonlinear buckling analyses are compared with those of experiments of the CFRP isogrid cylindrical shells, an agreement of both results are shown in Table 2. Furthermore, an optimum design of CFRP cylindrical shell under the compression load is also demonstrated. In the optimum problem, three design parameters, such as an orientation angle of cylindrical shell, the width and thickness of isogrid stiffeners are selected among the many design parameters and their optimum value are searched for decreasing the weight of CFRP isogrid shell subjected the constrain of some value of buckling load by the response surface method (RSM) combined with movingleastsquares(MLS).

ABSTRACT: The system of a steel plate bolted to a Reinforced Concrete (RC) shear wall goes by the name of a ‘Composite Steel Plate Shear Wall’ (CSPSW), which is used as the lateral resisting system in tall buildings. In
this system, the steel plate buckles under medium-strong earthquakes, which may lead to instability. However, the buckling load of steel plates is usually a limited criterion for the design of CSPSW. This paper reports a series of experiments on CSPSW. The experiments were used to investigate the buckling load of a steel plate bolted to one side of a high strength reinforced concrete panel. Furthermore, theoretical modeling, based on energy methods, was used to obtain the elastic buckling coefficients of steel plates with various aspect ratios under shear loading. The results were presented in graphical and tabular forms showing good agreement of theoretical modeling with experimental results. The elastic buckling coefficients can be used for determination of the number of bolts or the spacing between the bolts.

ABSTRACT: This paper describes the fabrication and testing of the composite isogrid stiffened cylinder. The purpose of the axial compression test was to identify various failure modes that are present in the structures such as rib crippling, skin (pocket) buckling, and general instability. The rib buckling was found to be the critical failure mode for the isogrid cylinder. The isogrid cylinder has been demonstrated to be tolerant to structural damage due to the multiplicity of load paths. The cylinder continued to resist compression loading even after one or more ribs had fractured. The imperfections to the cylinder resulted in reduced buckling resistance but this problem can be overcome by advancement in the manufacturing methods.

ABSTRACT: To get strong, stiff and light cylindrical shell, carbon fiber reinforced hierarchical orthogrid stiffened cylinders are designed and fabricated. The cylinder is stiffened by two-scale orthogrid. The primary orthogrid has thick and high ribs and contains several sub-orthogrid cells whose rib is much thinner and lower. The primary orthogrid stiffens the bending rigidity of the cylinder to resist the global instability while the sub-orthogrid stiffens the bending rigidity of the skin enclosed by the primary orthogrid to resist local buckling. The cylinder is fabricated by filament winding method based on a silicone rubber mandrel with hierarchical grooves. Axial compression tests are performed to reveal the failure modes. With hierarchical stiffeners, the cylinder fails at skin fracture and has high specific strength. The cylinder will fail at end crushing if the end of the cylinder is not thickened. Global instability and local buckling are well restricted by the hierarchical stiffeners.

ABSTRACT: In launch vehicle structures, for withstanding buckling failures due to the compressive loads and external pressure, integrally stiffened shell structures (waffle and isogrid shell structures) are employed. This paper discusses about the design of cylindrical and conical shaped isogrid structures subjected to axial compression and the external pressure and the effect of variation of design parameters like height of the triangle, skin thickness, rib width, rib depth etc. on the buckling load capacity. First, theoretical computation of the buckling load factor has been carried out using design equations for isogrid structure. A near optimum configuration is arrived at, which results in minimum equivalent weight thickness and positive margins of safety. By using inhouse software FEAST, a parametric modeling tool has been developed for modeling isogrid and waffle shell structures. Static analysis, buckling analysis and free vibration analysis have been carried out for both structures using FEAST software. By comparing the results, isogrid structures have less static displacement and more buckling load factor when compared with waffle structure.

ABSTRACT: This study is focused on the buckling behavior of spherical concrete shells (domes) under different loading conditions. The background of analytical analysis and recommended equations for calculation of design buckling pressure for spherical shells are discussed in this study. The finite element (FE) method is used to study the linear and nonlinear response of spherical concrete shells under different vertical and horizontal load combination buckling analysis. The effect of different domes support conditions are considered and investigated in this study. Several dome configurations with different geometry specifications are used in this study to attain reliable results. The resulted buckling pressures from linear FE analysis for all the cases are close to the analytical equations for elastic behavior of spherical shells. The results of this study show that geometric nonlinearity widely affects the buckling resistance of the spherical shells. The effect of horizontal loads due to horizontal component of earthquake is not currently considered in the recommended equation by The American Concrete Institute (ACI) to design spherical concrete shells against buckling. However, the
results of this study show that horizontal loads have a major effect on buckling pressure and it could not be ignored.

ABSTRACT: The steel stiffened segment in a steel–concrete connection joint is critical to the load capability of the cable-stayed bridge with hybrid girders. The research focused on the improvement of steel stiffened segments by investigating their failure reasons, mechanical behavior, and transmission efficiency. In order to achieve that, both the experiments and finite-element (FE) analysis of three classical types of stiffened segments subjected to axial compression were conducted, and FE results were consistent with test data. Effects of element sizes, geometric imperfections, and residual stresses were considered in FE models, and proper values for the imperfections were suggested. With refined models, transmission efficiency and stress concentration of three types of steel stiffened segments have been investigated. Segments with a U-shaped stiffener inserted T-stiffener and U-shaped stiffener circumscribed double T-stiffener are suggested for better force transmission and less local stress concentration. Furthermore, parameter studies on two suggested types above are carried out. Results show that the vertical plate could be thinning when the condition of stability is satisfied. Proper thickness of the vertical plate in a single T-stiffener and proper spacing between vertical plates in a double T-stiffener are given.

ABSTRACT: Ranging from agriculture to food processing, from mining to industrial processing, all these sectors have a need for the temporary storage of (dry) powdered, granular, and bulk materials between different stages of all kinds of manufacturing processes and between manufacturing process and transportation, or vice versa. Silos are therefore the perfect solution to meet this need, because they can easily store large volumes on a relatively limited floor space. Frequently, silos have a circular platform and are placed in elevated position. The latter can be achieved by a limited number of discrete equidistant supports around the barrel circumference. However, in such cases, large loads have to be transferred to the limited number of supports, causing locally high axial compressive stress concentrations, and consequently premature failure due to plastic yielding and/or elastic buckling (depending on the thickness of the silo wall). A possible answer to avoid these problems is to provide a partial-height U-shaped longitudinal stiffener above each support. Such stiffeners allow for a more gradual load transfer to the supports, increasing the maximum failure load. This paper aims to map the influence of the dimensions of such longitudinal stiffeners (i.e. the parameters of the cross-section and the height) on the failure behaviour of thick-walled silos. All results and findings are based on geometrically and materially non-linear analyses or GMNA performed with finite element software. The simulations indicate that correctly, for thick-walled silos, failure will always occur by (elasto-)plastic yielding. Depending on the longitudinal stiffener cross-section, the location of failure will occur in the stiffened zone of the silo just above the supports for silos.
with stiffeners with a small cross-section, whereas for stiffeners with larger cross-sections, failure occurs in the unstiffened zone just above the terminations of the stiffeners. In addition, the stiffener width in circumferential and radial direction have respectively an advantageous and a disadvantageous influence on the failure load. Finally, the stiffener height only has a positive impact on the failure load when failure occurs in the unstiffened silo wall. This can be addressed to the distribution of the supporting force over the entire circumference with higher stiffeners.

ABSTRACT: This work uses different finite element approaches to the free vibration analysis of reinforced shell structures, and a simplified model of a typical launcher with two boosters is used as an example. The results obtained using a refined one-dimensional (1D) beam model are compared to those obtained with commercial finite element software. The 1D models that are used in the present work are based on the Carrera Unified Formulation (CUF), which assumes a variable kinematic displacement field over the cross-sections of the beam. Two different sets of polynomials that correspond to Taylor (TE) or Lagrange (LE) expansions were used. The analyses focused on three reinforced structures: a stiffened panel, a reinforced cylinder and the complete structure of the launcher. The frequencies and natural modes obtained using one-dimensional models are compared to those obtained from classical finite element analysis. The classical FE models were built using a beam-shell or solid elements, and the results indicate that the refined beam models can in fact be used to investigate the behavior of very complex reinforced structures. These models can predict the shell-like modes that are typical of thin-walled structures that cannot be detected using classical beam models. The refined 1D models used in the present work provide results that are as accurate as those from solid FE models, but the 1D models have a much lower computational cost.

PARTIAL ARTICLE: Anyone designing high-performance cylindrical and conical-shell structures invariably wants to balance strength and low weight, along with several other characteristics including lowest-cost manufacturing. FEA and CAD software provide one way to shape complex forms, but these general-purpose programs work best when applied to a wider variety engineered structures and tasks.

Often hard-to-implement analysis methods may provide some assistance designing the cylindrical and conical shell structures traditionally found in aerospace products, such as rockets and launch vehicles. But these methods may not work equally well, if at all, designing structures that could be, for example, load carrying vacuum vessels or any thin-wall structure.

Software for shell structures: One particular program, Shell Structures Tools (SST), has been in development 40 years and addresses the lightweight, high-strength requirements, and more. Its start menu makes it easy to type in design requirements, and results are easy to understand and use in a format similar to Web pages. The software unifies design, manufacturing, and analysis based on classical, empirical, and FEA methods. It comprehensively and quickly produces a design along with production plans for the structure.

Shell structures designed by the software can be isogrid, waffle, monocoque, sandwich, honeycomb, or ring or stringer-rib stiffened. Several variations of those are possible. For example, sandwich structures can have fluted cores, honeycomb can have proprietary Hexcel cores, ribs can be stiffened with flanges and various skin-and-stringers can be used for shell stiffening.

When designing each structure, the software calls upon particular empirical, classical, and finite-element methods to size, analyze, and optimize about 11 characteristics the structures commonly need. This brief introduction to the software gives an idea of what designers would provide and what the software returns. The Start Menu box outlines typical inputs needed to design and analyze a shell. The inputs for about 10 categories typically include the shell geometry such as the large and small ID for a cone, and a length. If the shell includes cutouts such as round portholes, designers supply porthole diameters and locations, and whether or not the structure will include load-bearing doors (a yes or no selection). Local loads can be applied to the shell several ways such as, normal loads and bending moments.

Users select the construction material, which can include metals, composites, and their adhesives. Depending on the material, designers may have to supply material properties at temperature. For a complete list of the input criteria see http://www.machinedesign.com/md/images/SST-START-MENU-MD1.xls.

The software lops time off design work several ways. For instance, its unformatted inputs means users need not supply a CAD model. The dimensions typed into the Start Menu, actually an Excel spreadsheet, give enough information to get things started. Users are also asked to supply edge conditions, external loads, needed safety factors, structural configurations, identify critical-failure modes, modal-response requirements, construction methods, requirements for trade-offs, and tolerances for manufacturing and structural analysis.

Using runtime files, the software generates a best design and presents results in a Web site. Results are globally modified so users might, for example, adjust the manufacturing tolerances once and the software finds all calculations that use them before recalculating. The design is complete and comprehensive for the supplied loads the first time SST produces an output.
It is not difficult to run the software but it is preferable that my firm return to clients results to the spreadsheet Start Menu submitted by clients. Hence, the first turn-around may take a day or two. But after the program generates runtime files, iterations on the original design can be a matter of minutes. . . . (More is available but not reproduced here in order to save space.)

ABSTRACT: This paper presents an integrated experimental and computational study of the compression behavior of individual thin-walled metallic hollow spheres (MHS) with patterned distributions of microporosity. Quasi-static compression testing, including purely elastic loading, was conducted on two groups of individual MHS with two different sizes to examine the entire deformation process as well as the purely elastic response. Three-dimensional finite element modeling was then performed to investigate the effects of different microporosity distribution patterns on the MHS compression behavior and to understand the pertinent deformation and failure mechanisms. Results show that the Young's modulus and collapse stress of individual MHS with a uniform microporosity distribution decrease nonlinearly with porosity, which follows the same power-law functions developed for the porous wall material. For other patterned (i.e., vertical, horizontal, and random) distributions of microporosity involving localized weak wall sections, buckling commences at the weak sections, generating “buckling lines”, followed by buckling failure along these adjacent or converged “buckling lines”. Moreover, among the “buckling lines” generate some hinges that contribute to the increased load-bearing capability during the densification process. These findings can shed lights on the design, manufacturing, and modeling of individual MHS and MHS-based materials with specifically tailored engineering performance.

ABSTRACT: The results of FEM calculations of stability of thin–walled spherical shells are presented. A static and dynamic stability analysis was conducted. Hemispherical shells and spherical caps with various dilation angles, subjected to external pressure, were considered. For each shell calculated, various boundary conditions of support were analyzed: joint, fixed and elastically fixed support. In the calculations, an axisymmetric and random discretization of the model was accounted for. As a result of the calculations conducted for static loads, values of upper critical pressures and buckling modes of the shells were obtained. The results were presented for various shell thicknesses. The FEM solutions were compared to the available results obtained with analytical and numerical methods, showing a good conformity. Dynamic calculations were conducted for a triangular pulse load. On the basis of the Budiansky–Roth dynamic criterion of stability loss, values of upper dynamic critical pressures were obtained. Shell buckling modes were determined as well.

ABSTRACT: For a cylindrical intersecting-latticed-three-dimensional-beam-system (ILTDBS) reticulated mega-structure braced with single-layer latticed membranous shell substructures, the formation method, form parameters and support styles are first studied in this paper. And a program, which can automatically generate the form of the structure, is developed. Then the geometrically nonlinear mechanical model and stability analysis program are developed, and the stabilities of the structure are investigated. The structural ultimate bearing capacities and buckling modes including overall buckling and local buckling are studied in detail by parametric analyses. And the laws of determination of various parameters of the structure with different spans on the critical state between local and overall buckling are obtained. The work will provide guidance in theory for practical applications of this kind of structure.

ABSTRACT: In the last decade, stretchable electronics evolved as a class of novel systems that have electronic performances equal to established semiconductor technologies, but can be stretched, compressed, and twisted like a rubber band. The compliance and stretchability of these electronics allow them to conform and mount to soft, elastic biological organs and tissues, thereby providing attractive opportunities in health care and biosensing. Majority of stretchable electronic systems use an elastomeric substrate to carry an ultrathin circuit mesh that consists of sparsely distributed stiff, thin-film electronic components interconnected by various forms of stretchable metal strips or low-dimension materials. During the fabrication processes and application of stretchable electronics, the thin-film components or nanomaterials undergo different kinds of in-plane deformation that often leads to out-of-plane or lateral buckling, in-surface buckling, or a combination of all. A lot of creative concepts and ideas have been developed to control and harness buckling behaviors, commonly regarded as pervasive occurrences in structural designs, to facilitate fabrication of stretchable structures, or to enhance stretchability. This paper provides a brief review of recent progresses on buckling analysis in stretchable electronics. Detailed buckling mechanics reveals important correlations between the geometric/material properties and system performance (e.g., mechanical robustness, deformability, structural architecture, and control). These mechanics models and analysis provide insights to design and optimize stretchable electronics for a wide range of important applications.

ABSTRACT: A Generalized Beam Theory (GBT) approach is derived that performs automated, quantitative modal decomposition of thin-walled members with an open cross-section. The technique extracts modal amplitudes and modal participation factors from any 3D displacement field, for example from finite element analysis or point clouds measured in the lab during a test to collapse. Thin-walled members exhibit deformation that can be represented as combinations of cross-sectional and global buckling modes. It is useful to quantitatively decompose these modes for strength prediction and design code development. Conventionally, buckling mode participation has been determined by visual inspection. This process is subjective and tedious since the person conducting the inspection is often dealing with many models or experiments. Taking advantage of GBT kinematics, the proposed method distinguishes itself by using only the GBT cross-section deformation modes instead of member-wise basis functions. The method is by nature applicable to different boundary and loading conditions without recalculating of basis functions. The mechanics are formulated to show that the method is supported by GBT kinematic assumptions, which ensures its general applicability. The approach is implemented in a Graphical User Interface (GUI) that accepts a thin-walled member 3D displacement field as input and then calculates modal participation factors, i.e., for member local, distortional, and global (Euler) buckling.

References listed at the end of the paper:
Nedelcu, M., and Cucu, H. L. (2014). “Buckling modes identification from FEA of thin-walled members using only GBT cross-sectional deformation modes.” Thin-Walled Structures, Coupled Instabilities in Metal Structures, 81, 150–158.

ABSTRACT: Failure in cold-formed steel beams is generally initiated by one of three instabilities: local, distortional, or lateral-torsional buckling. For cold-formed steel joists, purlins, or girts, when the compression flange is not restrained by attachment to sheathing or paneling, distortional buckling may be the predominant failure mode. Experimental results on cold-formed steel beams with unrestrained compression flanges are scarce. Therefore a series of distortional buckling tests on cold-formed steel C and Z sections in bending was conducted to establish the capacity in distortional buckling failures. Test details were selected to allow distortional buckling to form, but restrict lateral-torsional buckling to the extent possible. These distortional buckling tests also provide a direct comparison against the local buckling tests previously performed by the writers. As expected, large strength reductions are observed in the tested specimens when distortional buckling initiated the failure instead of local buckling. U.S., Canadian, and joint North American standards for design, which are known to primarily focus on local buckling, provided unconservative predictions of the observed strength. The Australian/New Zealand Standard and the direct strength method, which provide explicit methods for calculating the capacity in the distortional buckling mode, provided reasonably accurate and reliable predictions.

INTRODUCTION: Japan is in a seismically active area and experiences many damaging earthquakes with loss of life. In 1995, the Hyogoken-Nanbu earthquake caused major destruction in Kobe City and in 2011 the Great Eastern Japan earthquake and tsunami caused major destruction in the Pacific coast areas of northeastern Japan. Additionally, recent relatively less destructive earthquakes include the 2003 Tokachi-Oki earthquake, the 2004 Niigataken Chuetsu earthquake, the 2005 Miyagi-oki earthquake, the 2007 Noto-Hanto earthquake, and the 2007 Niigataken Chuetsu-Oki earthquake. In particular, the Great Eastern Japan, Noto-Hanto, Miyagi-oki, and Niigataken-Chuetsu-Oki earthquakes occurred near nuclear power facilities and have been accompanied by enhanced public concern for seismic safety of nuclear plants. Within the Japanese national government, the Nuclear Safety Commission revised the Regulatory Guide for Reviewing Seismic Design of Nuclear Power Reactor Facilities (Nuclear Safety Commission of Japan, 2006) in 2006. This revised Regulatory Guide required seismic safety design of buildings, structures and equipment for larger seismic motions. In addition, seismic probabilistic safety assessment (seismic PSA) (American Nuclear Society, 2007; Atomic Energy Society of Japan, 2007) was urged, for which accurate evaluation techniques for seismic response of equipment installed in the nuclear power plants were needed. Large cylindrical liquid storage tanks in nuclear power plants are classified as equipment requiring high seismic safety because many are containers storing cooling water used in normal plant operation and in accidents. Their seismic evaluation is done on the basis of the Technical Codes for Aseismic Design of Nuclear Power Plants (Japan Electric Association [JEA], 2008) published by the Japan Electric Association. The seismic evaluation methods used in the conventional seismic design of the tanks (Kanagawa Prefecture, 2002; High Pressure Gas Safety Institute of Japan [KHK], 2003; Architectural Institute of Japan [AIJ], 2010) such as the Technical Codes examine the bending vibration mode (beam-type vibration) which mainly affects the seismic resistance of the tanks, but they do not consider high order vibration modes (oval-type vibration) which are excited in the tank wall by large vibrations and cause oscillation patterns that look like petals of a flower. Therefore, it is necessary to reveal the influence of oval-type vibration on vibration characteristics and seismic safety and to consider the vibration in the seismic design of the tanks (Japan Society of Civil Engineers, 1989). However, research on oval-type vibration has only been of academic interest,
including reports on fluid-structure interaction which causes oval-type vibration (Japan Society of Mechanical Engineers, 2003) and nonlinear behavior of oval-type vibration (Chiba, 1993). Though analysis techniques such as finite element methods are available as seismic evaluation methods at present, numerical seismic analysis of the tanks considering oval-type vibration has not been established because advanced techniques such as fluid-structure interaction analysis and nonlinear dynamic structure analysis are needed to simulate the oval-type vibration behavior. In addition, capacity to resist buckling is an important evaluation item in seismic design of cylindrical liquid storage tanks. Buckling is a dangerous mode for tanks which drastically lowers their structural strength (proof force) and collapses their geometries. In the ultimate buckled state and post-buckling, the cylindrical liquid storage tanks are deformed largely and display nonlinear inelastic behavior. Therefore, it is desirable to take into account the nonlinear inelastic dynamic behavior when evaluating seismic safety of the tanks. The conventional seismic design of tanks (Kanagawa Prefecture, 2002; KHK, 2003; JEA, 2008; AIJ, 2010) uses evaluation equations for static buckling derived from static buckling tests and the assumption of a linear response. However, the evaluation equations have not been validated sufficiently from the viewpoint of the dynamic liquid pressure effect in tanks subjected to seismic motions. Though a few dynamic experiments and development of numerical methods for buckling of cylindrical liquid storage tanks were done in the past, the developed numerical methods could simulate the experimental results only qualitatively (Fujita et al., 1992; Toyoda et al., 1997). As described above, the conventional seismic design assumes linear behavior of the tanks and does not include nonlinear behavior in post-buckling. However, it is necessary to develop accurate seismic response analysis methods for the cylindrical liquid storage tanks to ensure seismic safety and conduct accurate seismic PSA for mega earthquakes. Therefore, an accurate dynamic analysis method to evaluate dynamic nonlinear behavior of the cylindrical liquid storage tanks subjected to seismic motions was proposed and validated by the dynamic experiment in this chapter. The research was done for the liquid storage tanks installed in nuclear power plants such as refueling water tanks and condensate water tanks. In this chapter, previous studies are overviewed and then sequential research findings on the dynamic analysis method are summarized. First, the seismic damage modes of the cylindrical liquid storage tanks are explained briefly. Especially buckling modes caused by earthquakes are introduced. Secondly, the vibration behavior of the tanks is explained. Thirdly, previous studies are overviewed with regard to vibration characteristics and seismic evaluations. Special focus is given to the seismic response analysis and dynamic buckling evaluation. Fourthly, research studies concerned with oval-type vibration are summarized. Finally, the author’s study regarding dynamic nonlinear analysis method for seismic response of the cylindrical liquid storage tanks is described and the method is shown to be suitable for actual tanks based on comparison with experimental results.

ABSTRACT: A review is made of the development of methods used to examine the response of steel frame structures to statically applied loads. The various possible alternatives in terms of rigor and complexity are defined and key effects — especially the role of connections — discussed. Both multistorey and low-rise frames are considered. A section of the paper contrasts the relative lack of attention paid to a number of “neglected features” with the plethora of publications devoted to the analysis of 2-dimensional, bare steel, rigid jointed structures.

ABSTRACT: Frames are possibly the most common forms of man-made engineering structures. They are formed by joining one-dimensional members together. Since the early work of Euler, engineers started to realize that the strength of a member under compression does not only depend on the material yield stress, but also on the Young’s modulus of elasticity. The introduction of steel material and other metals makes the consideration more important because of their relatively slender dimensions. From the vision of the current computer age, this paper is addressed to a review and summary of the work conducted on the non-linear analysis and design of steel frames in the past few decades.

ABSTRACT: The system-based design of steel structures using advanced analysis leads to a more efficient structural design process and achieves a more uniform level of structural system reliability. The main impediment to adopting this method in practical applications is the apparent difficulty in assigning an
appropriate resistance factor to structural systems. In this paper, the reliability assessment and derivation of system resistance factors for a series of 3D low-to-mid-rise steel frames are presented, taking into account the inherent uncertainties in material and geometric properties, and the model uncertainty of advanced analysis. Braced and unbraced (sway) frames with regular and irregular configurations are analysed under gravity loads and the system resistance factors are derived for different target reliability levels. The frames are selected to provide different system failure modes such as sway instability and/or member failure. Recommendations are made for the appropriate target reliabilities and associated system resistance factors for use in designing 3D steel frames at system level by advanced analysis.

INTRODUCTION: Taking into account the stiffness and inertia forces, dynamic behaviour of structures can be investigated. Dynamic investigation usually starts with an example of free vibration. It means to evaluate the natural frequency. The simplest stability problem of structures is buckling of a column. This problem can be arranged preparing the equilibrium conditions on a deformed structure. In general, however, for the evaluation of the stability problems strains should be evaluated for a deformed differential element what means to apply geometric non-linear theory.
Combination of dynamics and stability yields in a lot of problems: dynamic buckling, dynamic post buckling behaviour, parametric resonance, etc. Introduction example – vibration of a column loaded in compression is simple but its investigation still represents a lot of problems.
The natural frequency can be measured by using rather simple equipment. The comparison of frequencies measured experimentally and evaluated numerically is the basis of non-destructive methods for investigation of structure properties. Generally, it can be said that in structural design stability effects have to be taken into consideration. These two ideas are the reason for our investigation of the combination of vibration and stability.
Leonard Euler was probably the first scientist who had analyzed stability problems. The former solutions are supposed to be the linear stability. It means that we suppose an ideal structure. The differences between theory and reality inspired researchers to search for more accurate models. Especially the slender web as the main part of thin-walled structure has significant post-buckling reserves and it is necessary to accept a geometric non-linear theory for their description. The problem of the vibration of the non-linear system was formulated by Bolotin [2]. Burgreen [3] analysed the problem of the vibration of an imperfect column in early 50's. Some valuable results have been achieved by Volmir [7]. Combination of dynamics and stability is still a subject of research all over the world.

ABSTRACT: In this paper, we report a novel nanoscale wrinkle-structure fabrication process using fluorocarbon plasma on poly(dimethylsiloxane) (PDMS) and Solaris membranes. Wrinkles with wavelengths of hundreds of nanometers were obtained on these two materials, showing that the fabrication process was universally applicable. By varying the plasma-treating time, the wavelength of the wrinkle structure could be controlled. Highly transparent membranes with wrinkle patterns were obtained when the plasma-treating time was <125s. The transmittances of these membranes were >90% in the visible region, making it difficult to distinguish them from a flat membrane. The deposited fluorocarbon polymer also dramatically reduced the surface energy, which allowed us to replicate the wrinkle pattern with high precision onto other membranes without any surfactant coating. The combined advantages of high electron affinity and high transparency enabled the fabricated membrane to improve the performance of a triboelectric nanogenerator. This nanoscale, single-step, and universal wrinkle-pattern fabrication process, with the functionality of high transparency and ultra-low surface energy, shows an attractive potential for future applications in micro- and nanodevices, especially in transparent energy harvesters.

ABSTRACT: The generation of nano-microstructured surfaces is a current challenge in polymer science. The fabrication of such surfaces has been accomplished mainly following two different alternatives i.e., by adapting techniques, such as molding (embossing) or nano/microimprinting, or by developing novel techniques including laser ablation, soft lithography or laser scanning. Surface instabilities have been recently highlighted as a promising alternative to induce surface features. In particular, wrinkles have been extensively explored for this purpose. Herein, we describe the preparation of wrinkled interfaces by confining a photosensitive monomeric mixture composed of monofunctional monomer and a crosslinking agent within a substrate and a cover. The wrinkling characteristics can be controlled by the monomer mixture and the experimental conditions employed for the photopolymerization. More interestingly, incorporation within the material of a functional copolymer allowed us to vary the surface chemical composition while maintaining the surface structure. For that purpose we incorporated either a fluorinated copolymer that enhanced the surface hydrophobicity of the wrinkled interface or an acrylic acid containing copolymer that increased the hydrophilicity of the wrinkled surface. Finally, the role of the hydrophobicity on the bacterial surface adhesion will be tested by using Staphylococcus aureus.

Phys substrates form in the vicinity of positive disclinations. In free positive Gaussian curvature, whereas negative disclinations give rise to negative curvature. Here, we present a

ABSTRACT: Emergent three-dimensional structure. Standard lore dictates that positive disclinations are associated with positive Gaussian curvature, whereas negative disclinations give rise to negative curvature. Here, we present a diblock copolymer system exhibiting a striped columnar phase that preferentially forms wrinkles perpendicular to the underlying stripes. In free-standing films this wrinkling behavior induces negative Gaussian curvature to form in the vicinity of positive disclinations.

SIGNIFICANCE: Diblock copolymers, polymers made by covalently bonding two otherwise immiscible polymers together, are prized for their robust ability to self-assemble into highly ordered geometric structures. Likewise, there has been recent interest in the ability to control the global geometry of a surface, merely by modifying its local microstructure. Here, we take advantage of the defect structure arising from a slow annealing of a thin film of cylinder-forming diblock copolymers as a means of guiding the geometry of an emergent three-dimensional structure.

ABSTRACT: Recently, there has been renewed interest in the coupling between geometry and topological defects in crystalline and striped systems. Standard lore dictates that positive disclinations are associated with positive Gaussian curvature, whereas negative disclinations give rise to negative curvature. Here, we present a diblock copolymer system exhibiting a striped columnar phase that preferentially forms wrinkles perpendicular to the underlying stripes. In free-standing films this wrinkling behavior induces negative Gaussian curvature to form in the vicinity of positive disclinations.

ABSTRACT: A non-Euclidean plate is a thin elastic object whose intrinsic geometry is not flat and hence has residual stresses arising from being embedded in three dimensional space. Recently, there has been interest in using localized swelling to induce residual stresses that shape flat objects into desired three dimensional structures. A fundamental question is whether we can use the mathematical theory of non-Euclidean plates to deduce the three dimensional configuration of the swelling sheet given the exact knowledge of the imposed geometry. We present and summarize the results of recent mathematical studies on non-Euclidean plates with imposed constant negative Gaussian curvature in both annular and disc geometries. We show in the Föppl–von Kármán approximation to the elastic energy there are only two types of global minimizers – flat and saddle shaped deformations – with localized regions of stretching near the boundary of the domain. We also show that there exist n-wave local minimizers that closely resemble experimental observations and have additional regions of stretching near lines of inflection. Furthermore, in the Kirchhoff approximation to the elastic energy, we show that there exists exact isometric immersions with periodic profiles. The number of waves in these configurations is set by the condition that the bending energy remains finite and grows approximately exponentially with the radius of the annulus. For large radii, these shape are energetically favorable over saddle shapes and could explain why wavy shapes are selected in crochet models of the hyperbolic plane. The predicted morphologies however differ from what is observed in experiments on hydrogel disks highlighting the need for further theoretical studies.

Sanjib C. Chowdhury, Bazle Z. (GAMA) Haque and John W. Gillespie Jr. [Center for Composite Materials (UD-CCM), University of Delaware, Newark, DE 19716, USA], “Molecular simulations of the carbon nanotubes intramolecular junctions under mechanical loading”, Computational Materials Science, Vol. 82, pp 503-509, 2014

ABSTRACT: In this paper, mechanical responses of the carbon nanotubes (CNTs) intramolecular junctions (IMJs) under three generic modes of mechanical loadings – tension, compression, and torsion have been studied using molecular dynamics simulations. (5,5)-(10,0), (7,7)-(14,0), (10,10)-(20,0) armchair–zigzag and (8,0)-(6,0) zigzag–zigzag IMJs have been simulated by connecting two constituent CNTs with pentagon and heptagon
rings. Classical molecular dynamics based on the velocity-Verlet algorithm has been used to solve the
Newtonian equation of motion and carbon–carbon interaction in the CNT has been modeled by the Brenner
potential. Mechanical properties, particularly stiffness and maximum force/torque and failure modes for
different loading conditions are studied. Simulation results show that stiffness of the IMJ falls between those of
the constituent CNTs. Compressive failure load of the IMJ is lower than either of the constituent CNTs.
However, failure loads and damage modes of the IMJs under tensile and torsional loadings depend on the
transition region in the IMJs.

ABSTRACT: A general minimum-weight cylindrical structural layout for the support of any combination of axial and torsional loading has been developed. The principal intention in this work is to provide a test case for 3-dimensional numerical topological optimization. It is anticipated that the solution may present a challenge, since for the small angular spacing of the truss elements the internal radial force component is always of the order of magnitude of the angular spacing for any arbitrary selected pair of helix families. Moreover for a wide range of solutions slender members are an essential part of the topology. A novel finite element topology optimization procedure is presented based on the application of Beta probability density and cumulative distribution functions. The procedure utilizes a family of Beta functions which provide a smooth transition from a uniform to a bi-modal density distribution, with constant probability mean to conserve constant mass.

ABSTRACT: Instead of the usual neglecting, this study takes advantage of the second-order axial strain terms in the elastic constitutive equation of three-dimensional truss. This leads to higher-order terms on the resulting unbalanced force and on its corresponding tangent stiffness. The finite element procedure and updated Lagrangian descriptions are utilized with the new stiffness matrix. Furthermore, governing equilibrium equations are solved by using cylindrical arc-length approach. The validity of the proposed algorithm is checked by numerical examples. The outcomes indicate that the authors’ formulation possesses the ability to trace the equilibrium path completely. Moreover, the obtained answers are identical with the exact results of other researchers.

ABSTRACT: Availability of block-type syntactic foam buoyancy units has facilitated a range of underwater activities otherwise deemed as impossible, e.g., dive to the bottom of the oceans in 2012. But buoyancy units which require a vessel-type configuration still remain a subject of research. High specific properties, resistance to degradation in water, and flexible fabrication methods become valuable factors when underwater applications are considered. Light weight is critical for submersibles as this leads to increased pay-load and to enlarged operational envelope. All of that points towards the use of composite materials.

In this context the Chapter deals with the strength, buckling and structural optimization of externally pressurized bowed-out cylinders, domed end closures onto cylinders, and toroidal shells of closed cross-section subjected to hydrostatic external pressure. It is assumed that shells are from Carbon Fibre Reinforced Plastics (CFRPs). The work is primarily numerical but some details about the manufacture, testing and analyses of filament wound and draped CFRP heads carried out at Liverpool University are provided. The issues regarding the sensitivity of buckling pressures to the initial geometric imperfections, First Ply Failure, and the Last Ply Failure are also discussed.

ABSTRACT: Postbuckling behavior of three-dimensional (3D) braided rectangular plates subjected to biaxial compression is presented. The 3D braided composite may be treated as a cell system, and the geometry of each cell is deeply dependent on its position in the cross section of the plate. Based on Reddy’s higher-order shear deformation plate theory and general von Kármán–type equations that include the initial geometric imperfection of the plate, a perturbation technique is employed to determine postbuckling equilibrium paths of 3D braided rectangular plates. The results reveal that the geometric and physical properties have a significant effect on the postbuckling behavior of braided composite plates.

ABSTRACT: The nonlinear governing equations of rotationally-restrained laminated composite plates with imperfection are presented by the Galerkin method, and they are solved by employing the Newton–Raphson method for the post-buckling analysis. The considered laminates are symmetric, and they are loaded in pure in-plane shear or combined in-plane shear and compression. The deformation shape function of the restrained plates is obtained through a linear combination of vibration eigenfunctions of simply supported and clamped beams along either the longitudinal or transverse direction of plates. The validity study shows that the presented method is effective for performing the nonlinear analysis of laminates with all four edges elastically-restrained against rotation. A parametric study is conducted to evaluate the effect of rotational spring stiffness, material properties, and fiber orientation under pure in-plane shear as well as the loading ratio under combined shear and compression on the nonlinear static and post-buckling behavior of rotationally-restrained laminates. The proposed solution for nonlinear static analysis of rotationally-restrained composite plates with imperfection is accurate and effective, as demonstrated by the comparisons with the predictions by the finite element analysis, and combined with the discrete plate analysis technique, it can be potentially applied to post-buckling analysis of FRP structural shapes.

ABSTRACT: Geometric imperfections have a significant effect on both buckling and strength capacities of structural members. It is essential to accurately measure the geometric imperfections for finite element simulation especially for thin-walled sections. This paper presents the procedure to measure and incorporate geometric imperfections into finite element models using ABAQS software package with the focus of attention for cold-rolled aluminium sections. Laser scanners are firstly used to measure geometric imperfections along high-precision tracks while recording the distances to corresponding points on the surface of specimen. The measurement lines are located around the cross-section. Subsequently, a MATLAB code is developed to incorporate the measured imperfection magnitudes into a perfect mesh of the finite element model. The Fourier series approximation is used in the longitudinal direction along measurement lines while the linear interpolation is used for flanges, lips and web in the transverse direction.

ABSTRACT: Enumeration search method (ESM) checks all possible combinations of design variables in a bottom-up approach until it finds the global optimum solution for the design conditions. In this paper an optimum design of a multilayered laminated plate made of unidirectional fibre reinforced polymer (FRP) composite subject to uniaxial compression is sought. ESM together with classical laminated plate theory (CLPT) has been used to find the lightest laminate for maximizing the buckling load capable of providing structural stability for a set target uniaxial compression load. The choice of the design variables is limited to 4 possible fibres orientation angles (0, 90, -45, +45) and the sequence of the laminate, making the problem an integer programming. Experimental and finite element analyses were used to verify the optimum solution. It has been shown that the exhaustive enumeration search method is a powerful tool for finding the global optimum design.

ABSTRACT: The local buckling capacity of fire exposed thin-walled steel cross sections is affected by the reduction in strength and stiffness due to elevated temperatures and the amplitude of the initial local imperfections. Several researchers have proposed design methods to calculate the capacity of the plates (i.e. web and flanges) that compose these steel members at elevated temperatures, but they used different shapes of steel plates (sides ratio a/b) and different amplitudes of local imperfections. This variability in hypotheses happens because there is no clear provision defining the numerical modeling procedure for fire design of steel plates in the codes (European or US). According to the theory of perfect plates, the critical load depends of the shape of the rectangular plate (e.g. the sides ratio a/b) and the corresponding buckling mode (number of half waves), the boundary and the loading conditions. This paper reviews the existing code provisions and compares the existing design models and their assumptions for thin-walled steel cross sections. Elements of the theory of perfect plates are presented. Parametric finite element analyses are then conducted on isolated steel plates at elevated temperatures to investigate the effect of the plate shape (a/b ratio) and imperfections (amplitude and number of half wave lengths). From the analysis, the governing parameter will be estimated (a/b vs imperfections) for simulation of isolated flanges and webs. Finally, recommendations for the numerical modeling of steel plates at elevated temperatures are proposed.

ABSTRACT: The nonlinear vibrations of Single-Walled Carbon Nanotubes are analysed. The Sanders-Koiter elastic shell theory is applied in order to obtain the elastic strain energy and kinetic energy. The carbon nanotube deformation is described in terms of longitudinal, circumferential and radial displacement fields. The theory considers geometric nonlinearities due to large amplitude of vibration. The displacement fields are expanded by means of a double series based on harmonic functions for the circumferential variable and Chebyshev polynomials for the longitudinal variable. The Rayleigh-Ritz method is applied to obtain approximate natural frequencies and mode shapes. Free boundary conditions are considered. In the nonlinear analysis, the three displacement fields are re-expanded by using approximate eigenfunctions. An energy approach based on the Lagrange equations is considered in order to obtain a set of nonlinear ordinary differential equations. The total energy distribution of the shell is studied by considering combinations of different vibration modes. The effect of the conjugate modes is analysed.

ABSTRACT: This paper presents a comprehensive study of the lateral compressive response of hexagonal honeycomb panels from the initial elastic regime to a fully crushed state. Expanded aluminum alloy honeycomb panels with a cell size of 9.53 mm, a relative density of 0.026, and a height of 15.9 mm are laterally compressed quasi-statically between rigid platens under displacement control. The cells buckle elastically and collapse at a higher stress due to inelastic action. Deformation then first localizes at mid-height and the cells crush by progressive formation of folds; associated with each fold family is a stress undulation. The response densifies when the whole panel height is consumed by folds. The buckling and crushing events are simulated numerically using finite element models involving periodic domains of a single or several characteristic cells. The models idealize the microstructure as polygonal, with double walls in one direction. The nonlinear behavior is initiated by elastic buckling while inelastic collapse that leads to the localization observed in the experiments occurs at a significantly higher load. The collapse stress is found to be mildly sensitive to various problem imperfections. The subsequent folding can be reproduced numerically using periodic domains but requires a fine mesh capable of capturing the complexity of the folds. The calculated crushing response is shown to better resemble measured ones when a 4 x 4 cell domain is used. However, the average crushing stress can be captured with engineering accuracy even from a single cell domain.

Aluminum films 150 nm thick have been deposited on polymethylmethacrylate (PMMA) substrates by a magnetron sputtering process. Parallel straight-sided wrinkles are induced by axial compression. The evolution from straight-sided to 'telephone-cord' wrinkles is experimentally investigated using optical microscopy. Finite element modeling of instability is introduced for analyzing the secondary bifurcation or buckling of straight-sided wrinkles. Imperfections based on a random combination of buckling eigenmodes are introduced in the finite element method (FEM) analysis to take into account secondary bifurcation. Because the perturbation of the imperfection is totally random and small, it is a more realistic approach for taking into account the roughness and flatness of the film. Moreover, the perturbation method can be applied more widely in some complex patterns of telephone-cord wrinkles. Good agreement is found between experimental observation and FEM calculations.

ABSTRACT: Novel designs for solar sails and star shades make use of thin films with large surface areas packed into finite volumes by introducing origami-like fold patterns. Predicting the deployed shape, deployment dynamics and mechanical stability of these structures requires an accurate modeling of the mechanical properties of the folds, instead of assuming perfect hinges like in rigid foldable origami. We have performed experiments in thin films with a single crease to investigate the underlying mechanics and characterize the mechanical properties of the fold. A parametric study was conducted on folding a Kapton film, showing that the neutral angle after folding can be rationalized as a function of the parameters in the folding process, but it evolves over time due to viscoelastic effects. Additionally, a framework has been established to quantify the hinge stiffness of a fold by its moment - angle relationship, showing a linear relationship regardless of the neutral angle. Finally an analytic model has been proposed by combining the hinge stiffness along with Elastica theories to predict the deflected shapes of folded thin films.

“Quantitative predictions of diverse wrinkling patterns in film/substrate systems”, Scientific Reports, Vol. 7, Article number 18081, 2017

ABSTRACT: A basic characteristic of stiff film/soft substrate systems is their ability to experience large deformation under compressive stresses, which inevitably leads to formation of patterns on the surface. Such pattern formation is the result of loss of stability and symmetry breaking. Knowledge on how such instabilities arise and evolve is essential to describe, understand, predict, and ultimately to design complex functional materials and structures, for example the fabrication of stretchable electronic devices and micro/nano-scale surface patterning control. In this paper, quantitative predictions of various instability pattern formations and evolutions, which involve highly nonlinear deformation and multiple bifurcations, will be presented based on advanced mechanical models and methods, from planar to curved geometry. The results can provide further insight into fundamental understanding in a whole view of a variety of surface patterning morphology and imply a potential way to facilitate the design of functional materials and structures by quantitatively harnessing surface instabilities.

ABSTRACT: Experiments on aluminum tubes with varying D/t ratios and their finite element simulation have been performed to study their collapse mechanism as well as the load compression and the energy absorption responses. Convergence studies with respect to model parameters like load step size, mesh density and boundary conditions have been established. Dependence of deformation characteristics and energy absorption response on boundary conditions (end fixity), geometrical parameter- D/t ratio, and material parameters - yield strength and tangent modulus, have been studied. Transition of deformation mode shapes from axisymmetric concertina mode to non axisymmetric diamond pattern owing to tube wall thickness eccentricity under perfectly axisymmetric tube end conditions has been simulated. Validation and comparison of numerical solution with the experimental results have been carried out.

ABSTRACT: In accordance with EN1993-1-1, in the definition of element classes, the tubular cross section
elements are considered as class 3 for cross section that respects the relation: \( d/t \leq 90e^2 \). If for any cross section this relation is not satisfied, the norm is not valid and the cross section is classified as a curved thin walled element – shell element. Thus the design is done according to EN 1993-1-6 normative. The paper presents some aspects regarding the shell design for a case study – a 30 m tall billboard pillar. The designing process is detailed in regard to the used analysis and the ultimate limit states checking. Considering the high stress concentration in the area of the segment joints, design of welded joints is also presented. The Finite Element Method (FEM) is applied as well, showing results in agreement with analytical ones.

ABSTRACT: The connection of a local support to an elevated cylindrical metal silo shell is a long-standing difficult problem in shell analysis, and most designs are based on simple ideas using past experiences of successes and failures. Smaller silo structures are often supported on local brackets attached to the side of the shell, but very few investigations of the behavior or strength of such an arrangement have ever been made. This paper presents an outline description of the behavior of a cylindrical steel shell that is discretely supported on several brackets, each rigidly connected to a stiff column or floor. The linear, materially nonlinear, geometrically nonlinear, and bifurcation behaviors of the shell under these conditions are outlined. In this problem the prebuckling deformations, bifurcation mode, and plastic collapse mode are each local. This configuration presents some interesting questions concerning the relative importance of geometric nonlinearity and geometric imperfections. The problem is recommended to advanced shell analysts as a benchmark test of their analysis and interpretation techniques.

ABSTRACT: Imposing curvature on crystalline sheets, such as 2D packings of colloids or proteins, or covalently bonded graphene leads to distinct types of structural instabilities. The first type involves the proliferation of localized defects that disrupt the crystalline order without affecting the imposed shape, whereas the second type consists of elastic modes, such as wrinkles and crumples, which deform the shape and also are common in amorphous polymer sheets. Here, we propose a profound link between these types of patterns, encapsulated in a universal, compression-free stress field, which is determined solely by the macroscale confining conditions. This “stress universality” principle and a few of its immediate consequences are borne out by studying a circular crystalline patch bound to a deformable spherical substrate, in which the two distinct patterns become, respectively, radial chains of dislocations (called “scars”) and radial wrinkles. The simplicity of this set-up allows us to characterize the morphologies and evaluate the energies of both patterns, from which we construct a phase diagram that predicts a wrinkle–scar transition in confined crystalline sheets at a critical value of the substrate stiffness. The construction of a unified theoretical framework that bridges inelastic crystalline defects and elastic deformations opens unique research directions. Beyond the potential use of this concept for finding energy-optimizing packings in curved topographies, the possibility of transforming defects into shape deformations that retain the crystalline structure may be valuable for a broad range of material applications, such as manipulations of graphene’s electronic structure.

ABSTRACT: At present molecular dynamics (MD) simulations are the major tools used to investigate the mechanical behaviour of fullerenes. In this study, the energy changes of three fullerene balls, C60, C80 and C180, under uniform inflation/deflation and axial tension/compression, are investigated using the second-generation Brenner potential. The energy changes can be precisely described by a cubic function of the inflation/deflation strain or tension/compression deflection. A spherical shell, the continuum model of the fullerene balls, is established and analysed by means of non-linear elasticity theory. The results of calculations using this model are in good agreement with those of MD simulations. A regular non-perturbative model for wrinkling in highly bendable sheets. ABSTRACT: This paper investigates the postbuckling and free vibration response of geometrically imperfect multilayer nanobeams. The beam is assumed to be subjected to a pre-stress compressive load due to the manufacturing and its ends are kept at a fixed distance in space. The small-size effect is modeled according to the nonlocal elasticity differential model of Eringen within the nonlinear Bernoulli-Euler beam theory. The constitutive equations relating the stress resultants to the cross-section stiffness constants for a nonlocal multilayer beam are developed. The governing nonlinear equation of motion is derived and then manipulated to be given in terms of only the lateral displacement. The static problem is solved for the buckling load and the postbuckling deflection in terms of three parameters: Imperfection amplitude, size, and lamination. A closed-form solution for the buckling load in terms of all of the beam parameters is developed. With the presence of imperfection and size effects, it has been shown that the buckling load can be either less or greater than the Euler buckling load. Moreover, the free vibration in the pre and postbuckling domains are investigated for the first five modes. Numerical results show that the effects of imperfection, the nonlocal parameter, and layup on buckling loads and natural frequencies of the nanobeams are significant.

"A study of imperfect cylindrical steel tubes under global bending and varying support conditions", Eighth International Conference on Advances in Steel Structures, Lisbon, Portugal, July 22-24, 2015

ABSTRACT: This paper presents the findings of a computational study into the effect of different support conditions on the behavior of imperfect cylindrical steel tubes under global bending. The research focuses on understanding the structural stability and the influence of support configurations on the tubes' performance. The results highlight the importance of considering imperfections in the design of such structures to ensure safety and efficiency.
conditions and geometric imperfections on the nonlinear elastic stability of tubular members of varying length under global bending. Using the finite element analysis software ABAQUS, the tubular member was modelled as an isotropic thin-walled cylindrical steel shell and subjected to a uniform bending moment distribution. The classical elastic critical buckling moment, the linear bifurcation moment and the nonlinear buckling moment were computed and the imperfection sensitivity under the linear buckling eigenmode was examined. The study demonstrates that the support conditions at the edges have a significant effect on the predicted buckling moment for short tubes, but that this influence vanishes for longer tubes. The effect of initial geometric imperfections on the nonlinear buckling strength was found to be sensitive to the tube length. The strength of longer tubes was much reduced, but in shorter ones, the effect was neutral or mildly beneficial. Overall, tubular members under global bending do not appear to be as imperfection-sensitive as those under uniform axial compression.

ABSTRACT: The laminated composite lay-up design typically involves trade-offs between material selection, thickness of the layer, orientation of the layers, and the stacking sequence. Finding the right structural concept early in the design process leaves resources for the detailed design. Many structural members made of laminated composite materials have the form of thin walled cylindrical shells that are prone to buckling. Thus it is desirable to find structural designs that satisfy global requirements for structural stability early in the design phases. In this work, thin-walled cylindrical composite shells under different loading conditions have been studied for structural stability. The simulation is performed with a shell facet model implemented in the ESAComp software. Preliminary design tools for structural stability of thin-walled cylindrical composite shells are demonstrated and discussed.

ABSTRACT: Rigid-foldable structures are foldable surfaces consisting of rigid panels and hinges, thus can be used for wide variety of deployable structures without relying on flexible materials. In this paper, we present a family of rigid-foldable collapsible cylindrical polyhedra which is of great interest of structural engineering field. The symmetry operations in order to synthesize the cylindrical structures and their space filling tessellation are shown.

ABSTRACT: The steel silos are interesting complex facilities. In order to ensure unloading of whole amount of stored product by gravity, the steel silos are often placed on supporting frame structure. Values of stresses in the joints between the thin walled shell and supporting frame elements are very high. It can causes local loss of stability in the shell. To prevent its local buckling, many designers put stiffening elements above the supports. Here the question is how high should be the stiffening elements? The right solution is that they should reach that level till which the values of the meridional normal stresses above the supports and in the middle between them are equalized. Under this level the cylindrical shell will be considered as a ring beam, stiffened by elements above the supports. Above it, the cylinder can be calculated as continuously supported shell. But where is this level? A lot of researchers worked on values and way of distribution of normal meridional stresses above the supports of the cylindrical shells. As a result of their efforts are determined critical height Hcr of the shell and the ideal position H1 of intermediate stiffening ring. But these heights are considerably different between each other. To which of them our vertical stiffening elements should achieve?

“Buckling and vibration of composite lattice elliptical cylindrical shells”, Journal of Materials Design and
ABSTRACT: An approach to the finite element study of the buckling and dynamic behaviour of composite lattice cylindrical shells with elliptical cross sections is presented in this paper. The lattice shells are modelled as three-dimensional frame structures composed of curvilinear ribs using beam finite elements. A specialised algorithm is developed to generate the finite element model of the lattice shells based on multiple use of the repeating unit cell of the composite lattice structure. Using this model, the buckling behaviour of the shells subjected to axial loading and transverse bending are investigated. Fundamental frequencies of axial and transverse vibrations of the shells with a massive rigid disk attached to their ends are determined based on the modelling approach proposed in this work. The effects of parameters of the lattice structure on the values of critical buckling loads, buckling and vibration mode shapes, and the fundamental frequencies are examined using parametric analyses. Based on the computations, the angles of orientation of helical ribs delivering maximum critical loads and fundamental frequencies are identified. The results of this study can be applied to the design of the composite tubular bodies of spacecraft made in the form of cylindrical lattice shells with elliptical cross sections.

ABSTRACT: In this paper, experimental investigation of two new structural design solutions with the aim of improving crashworthiness characteristics of cylindrical metal tubes is performed. In the first design method, a rigid steel ring is press-fitted on top of circular aluminum tubes. When this arrangement of dissipating energy is...
subjected to axial compression, the rigid ring is driven into the cylindrical tube and expands its top area; then, plastic folds start shaping along the rest of the tube length as the compression of the structure continues. In the second design method, wide grooves are cut from the outer surface of steel thick-walled circular tubes. In fact, this method converts thick-walled tubes into several thin-walled tubes of shorter length, being assembled together coaxially. When this energy absorbing device is subjected to axial compression, plastic deformation occurs within the space of each wide groove, and thick portions control and stabilize collapsing of the whole structure. In the present study, several specimens of each developed design methods with various geometric parameters are prepared and compressed quasi-statistically. Also, some ordinary tubes of the same size of these specimens are compressed axially to investigate efficiency of the presented structural solutions in energy absorption applications. Experimental results show the significant efficiency of the presented design methods in improving crashworthiness characteristics and collapse modes of circular tubes under axial loading.

ABSTRACT: Shell structures are usually formed from concrete, steel and nowadays also from many others materials. Steel is typically used in the structures of chimneys, reservoirs, silos, pipelines, etc. Unlike concrete shells, steel shells are regularly stiffened with the help of longitudinal and/or ring stiffeners. The authors of this paper investigated steel cylindrical shells and their stiffening with the use of ring stiffeners. The more complete the stiffening, the more closely the shell will act to beam theory, and the calculations will be much easier.
However, this would make realization of the structure more expensive and more laborious. The target of the study is to find the limits of ring stiffeners for cylindrical shells. Adequate stiffeners will eliminate semi-bending action of the shells in such way that the shell structures can be analyzed with the use of numerical models of the struts (e.g., by beam theory) without significant divergences from reality. Recommendations are made for the design of ring stiffeners, especially for the distances between stiffeners and for their bending stiffness.

ABSTRACT: Inflatable structures offer the potential of compactly stowing lightweight structures, which assume a fully deployed state in space. An important category of space inflatables are cylindrical booms, which may form the structural members of trusses or the support structure for solar sails. Two critical and interdependent aspects of designing inflatable cylindrical booms for space applications are i) packaging methods that enable compact stowage and ensure reliable deployment, and ii) rigidization techniques that provide long-term structural rigidity after deployment. The vast literature in these two fields is summarized to establish the state of the art.

ABSTRACT: The study investigates the behaviour of short, thin-walled laminated C-columns under eccentric compression. The tested columns are simple-supported. The effect of load inaccuracy on the critical and post-
critical (local buckling) states is examined. A numerical analysis by the finite element method and experimental tests on a test stand are performed. The samples were produced from a carbon-epoxy prepreg by the autoclave technique. The experimental tests rest on the assumption that compressive loads are 1.5 higher than the theoretical critical force. Numerical modelling is performed using the commercial software package ABAQUS®. The critical load is determined by solving an eigen problem using the Subspace algorithm. The experimental critical loads are determined based on post-buckling paths. The numerical and experimental results show high agreement, thus demonstrating a significant effect of load inaccuracy on the critical load corresponding to the column’s local buckling.

ABSTRACT: An investigation on triggering mechanisms for the birdcaging failure mode of flexible pipes, used in offshore oil and gas production, is carried out. From previous experimental observations, a conjecture is made: the local axisymmetric instability of the external plastic layer, caused by the high radial loading which is internally applied due to the helical armor wires tendency to expand when the pipe is subjected to compression, would be this trigger. A simple instability onset criterion for the external plastic layer, namely, the polymer
intrinsic yielding limit stress, is proposed and assessed, analytically, numerically and experimentally for HDPE tubes. Then, previous birdcaging experimental observations are investigated further, focusing on the flexible pipe external plastic layer, to assess the proposed criterion. Strong evidences of validity are obtained.

ABSTRACT: Design models for local buckling of fire-exposed aluminum sections are currently lacking. Based on analyses with validated finite-element models, this paper investigates local buckling of extruded sections with stress-strain relationships representative for fire-exposed aluminum alloys. Due to the fact that these stress-strain relationships are more curved than at ambient temperature, existing design models developed for ambient temperature cannot be used for fire design. This paper presents a new design model for local buckling under fire conditions. The study concludes that the local buckling resistance decreases less fast than the plastic capacity at increasing temperature. This is mainly due to the fact that the ratio between the modulus of elasticity and the 0.2% proof stress increases with increasing temperature for structural aluminum alloys.

ABSTRACT: Steel silo failure is not a sporadic event in the industrial field. Sometimes the failure involves only a shell deformation that does not affect the structural integrity of the overall silos. In other cases, failure involves complete collapse of the structure that could affect the people's safety. In general three major causes of silo failure are identified: design errors, construction errors, and utilization errors. In this study, a buckling failure of the real silos used in a thermal power plant to store a granular solid material (limestone) is analysed. It has long been recognized that the buckling failure of the silos is due mainly to the eccentric discharge of its stored solid. The main reason for this kind of failure is due to the difficulty, in the design phase, to characterize the pressure distribution caused by eccentric solids flow (funnelling). In the present study, the pressures caused by eccentric discharge are characterized using the new rules of the European Standard EN 1991-4 that defines the “Actions in Silos and Tanks”. Using this new improved description of unsymmetrical pressures, it is now possible to perform relatively realistic calculations relating to this common but complicated shell buckling condition. The paper explores the structural behaviour leading to buckling during eccentric discharge and proposes a possible reinforcement design of the silos to minimize this kind of problems following the approach given in the European Standard EN 1993-1-6 “Strength and Stability of Shell Structures”.

ABSTRACT: In the presented work, the compressive behavior of circular cylinders, having certain size ratios and containing a notch with various configurations, was investigated through experimental and numerical studies. Nonlinear finite element analysis, using ABAQUS software, was conducted to evaluate the ultimate strength of the cylinders. The results were compared to those observed experimentally. The comparison of the numerical and experimental results showed that the nonlinear analysis results were more accurate than those established based on a linear analysis. The study also focuses on the deformed shape and stress distribution of the critical region in a notched cylinder for further consideration, e.g. repairing purposes.

“Experiment and design method on cold-formed thin-walled steel lipped channel columns with slotted web holes under axial compression”, The Open Civil Engineering Journal, Vol. 11, pp 244-257, 2017  
ABSTRACT: Cold-formed steel structural sections used in the walls of residential buildings and agricultural facilities are commonly C-shaped sections with web holes. These holes located in the web of sections can alter the elastic stiffness and the ultimate strength of a structural member. The objective of this paper is to study the buckling mode and load-carrying capacity of cold-formed thin-walled steel column with slotted web holes. Compression tests were conducted on 26 intermediate length columns with and without holes. The tested compressive members included four different kinds of holes. For each specimen, a shell finite element Eigen-buckling analysis and nonlinear analysis were also conducted. The influence of the slotted web hole on local and distortional buckling response had also been studied. The comparison on ultimate strength between test results and calculated results using Chinese cold-formed steel specification GB50018-2002, North American cold-formed steel specification AISI S100-2016, and nonlinear Finite Element method was made. Test results showed that the distortional buckling occurred for intermediate columns with slotted holes and the ultimate strength of columns with holes was less than that of columns without holes. The ultimate strength of columns decreased with the increase in transverse width of hole in the cross-section of member. The Finite element analysis results showed that the web holes could influence on the elastic buckling stress of columns. The shell finite element could be used to model the buckling modes and analysis the ultimate strength of members with slotted web holes. The calculated ultimate strength shows that results predicted with AISI S100-2016 and analyzed using finite element method are close to test results. The calculated results using Chinese code are higher than the test results because Chinese code has no provision to calculate the ultimate strength of members with slotted The calculated method for cold-formed thin-walled steel columns with slotted web holes are proposed based on effective width method in Chinese code. The results calculated using the proposed method show good agreement with test results and can be used in engineering design for some specific cold-formed steel columns with slotted web holes studied in this paper.

In-field post-earthquake performance observations of winery facilities in the Marlborough region, New Zealand, were documented following the 14 November 2016 Kaikōura earthquake and subsequent aftershocks. Observations presented and discussed herein include land damage to vineyards and the performance of winery building facilities, legged and flat-bedded storage tanks, barrel racking systems, and catwalks. A range of winery facilities were instrumented with tri-axial accelerometers to capture seismic excitations during aftershocks, with the specific aim to instrument different storage tanks having varying capacities and support systems to better understand the dynamic performance and actual forces experienced up the height of the tanks during an earthquake, with preliminary results reported herein.

ABSTRACT: The purpose of this work is to detail some methodologies applied for analysis of the seismic behaviour of existing bottom supported storage tanks and pipelines, under predominantly horizontal seismic actions. Developments on the established finite element method (FEM), permitted to analyse tanks and their liquid contents by two possible approaches: Ritz method coupled with FEM applied to an analytical solution of the tank-liquid system; FEM of the full system by modelling the liquid as a degenerated solid. Both formulations permit to determine seismic response envelopes. Further, some considerations on active control of cylinders by piezoceramic stacks of actuators are outlined, for potential uses in pipelines and tube-like structures.

ABSTRACT: This paper presents experimental studies on buckling of cylindrical shell models under axial and transverse shear loads. Tests are carried out using an experimental facility specially designed, fabricated and installed, with provision for in-situ measurement of the initial geometric imperfections. The shell models are made by rolling and seam welding process and hence are expected to have imperfections more or less of a kind similar to that of real shell structures. The present work thus differs from most of the earlier investigations. The measured maximum imperfections \( \delta_{\text{max}} \) are of the order of plus or minus \( 3t \) \( (t = \text{thickness}) \). The buckling loads obtained experimentally are compared with the numerical buckling values obtained through finite element method (FEM). In the case of axial buckling, the imperfect geometry is obtained in four ways and in the case of transverse shear buckling, the FE modelling of imperfect geometry is done in two ways. The initial geometric imperfections affect the load carrying capacity. The load reduction is considerable in the case of axial compression and is marginal in the case of transverse shear buckling. Comparisons between experimental buckling loads under axial compression, reveal that the extent of imperfection, rather than its maximum value, in a specimen influences the failure load. Buckling tests under transverse shear are conducted with and without axial constraints. While differences in experimental loads are seen to exist between the two conditions, the numerical values are almost equal. The buckling modes are different, and the experimentally observed and numerically predicted values are in complete disagreement.

ABSTRACT: This paper is devoted to a further investigation on a range of externally pressurised egg-shaped pressure hulls. Hulls are 2.561 m long, 1.767 m wide, and have uniform wall thickness varying from 10 to 80 mm with 5 mm increment. Series of numerical simulations and laboratory scale experiments are performed to systematically study the buckling of egg-shaped pressure hulls, along with the effect of wall thickness on the buckling. Volume and mass equivalent spherical pressure hulls are also proposed to make a like-for-like comparison with egg-shaped pressure hulls. The results show that egg-shaped pressure hulls seem to be applicable to deep sea manned/unmanned submersibles, especially to full ocean depth ones (11,000 m). Also, deep pressure hulls tend to buckle in an elastic–plastic regime, which is strongly affected by the wall thickness. References listed at the end of the paper:
The list of references is similar to that given in the next paper.

ABSTRACT: This study focused on the buckling of stainless steel spherical caps under uniform external pressure. Caps with a circular arc meridian have a nominal base diameter of 146 mm, nominal uniform wall thickness of 1 mm and nominal height of 37 mm. Six nominally identical laboratory-scale caps were fabricated, measured precisely and tested slowly. The buckling performances of such caps were studied experimentally and numerically, and the results show good agreement with each other. Furthermore, the buckling of 13 mass-equivalent caps of various heights were numerically analysed to identify the cap with the best load-carrying capacity. The results suggest that a spherical cap with height-to-base diameter ratio of 0.274 supports the
highest buckling load. Such a cap can be applied as an end-closure for cylindrical pressure hulls or as a manhole cover for manned cabins in deep-sea vehicles.

ABSTRACT: Thin spherical pressure hulls are used as a human occupancy in deep water applications. DNV and other standards specify the imperfection allowed for pressure hulls. Numerical analyses are carried out to find the buckling pressure for both perfect and imperfect thin spherical pressure hulls, considering the geometric and material non-linearities. It is observed that there is a huge variation in the elastic and inelastic buckling pressure in perfect spherical pressure hulls. Moreover, if the manufacturing imperfections are considered in the inelastic numerical analysis, still there is a reduction in the buckling pressure. Design criteria, for deep water pressure hulls, is that both buckling pressure and yield pressure must be greater than the design pressure. In the elastic analysis, if \( t/D > 0.006 \) buckling pressure is always greater than the yield pressure whereas in the inelastic analysis, the buckling pressure is falling below the yield pressure for all \( t/D \) ratios. Hence, inelastic numerical analysis with manufacturing imperfection has to considered in the design of deep water spherical pressure hulls of manned submersibles.

ABSTRACT: Civil Engineering thin cylindrical shells such as silos and tanks are normally subjected to axial compression that arises from a stored solid, wind, earthquake, self-weight or roof loads. The walls of these shells are very thin, generally of the order of 6 to 25 mm, and massively less than the radius, which is typically 5 to 30 m. They are thus very thin shell structures, like those of rockets, spacecraft, motor vehicles and aircraft. The commonest failure mode is elastic buckling under axial compression. It has long been known that the buckling strength of a thin cylindrical shell under axial compression is very sensitive to tiny deviations of geometry, reducing the buckling strength to perhaps 10 or 20% of the value for the perfect structure. A normal internal pressure usually accompanies the axial compression, caused by stored granular solids or fluids. At relatively low pressures, the elastic buckling strength under axial compression rises, but an elastic-plastic buckling phenomenon intervenes at higher pressures, causing a dramatic decrease in buckling resistance associated with an elephant’s foot collapse mode. To construct such large shells, the fabrication technique is generally the assembly of many rolled plates or panels, joined by short longitudinal welds and continuous circumferential welds. The process of welding produces a distinctive geometric imperfection form at each weld joint, which in turn is extremely detrimental to the shell axial buckling carrying capacity. The strength may be further reduced by slight misalignments between adjacent panels, or in bolted construction, by vertical and horizontal lap splices. Due to the pattern of loading, both the axial compression and internal pressure increase progressively down the wall. Accordingly, practical construction usually uses a stepped wall, formed from panels of uniform thickness, but with larger thicknesses at lower levels. Since the loading varies smoothly, but each panel has constant thickness, the critical location for buckling lies at the base of a panel. But the greater thickness of the lower panel can usefully enhance the buckling strength of the critical panel above it. This thesis presents an extensive computational study that examines all the above influences, divided into chapters that are outlined here. A full exploration of the effect of the cylinder length on the perfect and imperfect elastic buckling strength is presented in Chapter 3. In Chapter 4, the elastic-plastic buckling resistance of imperfect cylinders is described, including strain hardening. These lead to many capacity curves, for which the key parameters are extracted. The effect of internal pressure on the buckling resistance of imperfect elastic cylinders is explored in Chapter 5. Chapter 6 studies the effect of high pressures that produce elastic-plastic elephant’s foot buckling at circumferential welds in imperfect shells. Next, a step change in plate thickness is studied in Chapter 7 for imperfect butt jointed cylinders with and without the internal pressure. Chapter 8 presents an exploration of the effect of plate misalignments at a circumferential joint, as well as the full misalignment of a circumferential lap joint in bolted construction. These are investigated in both the elastic and elastic-plastic domains. The entire thesis is conceived in the context of EN 1993-1-6 (2007) and the ECCS Recommendations on Shell Buckling (2008). This research has shown significant weaknesses in both the concepts and the detailed rules of these standards. Many conditions are found where either the standard is unnecessarily conservative, or its safety margin may be too low. Thus, some new provisions are proposed for each of the above practical problems. These are expected to provide useful knowledge for the design of such structures against buckling in the future.

ABSTRACT: The present study investigates the non-linear behavior of spherical shells under the influence of static circular ring loads. It is assumed that the material is isotropic and linearly elastic. The differential equations comprising the equilibrium equations, constitutive laws and kinematic equations are converted into non-linear algebraic equations by employing the method of finite differences. Respective non-linear algebraic equations are solved numerically by using the Newton–Raphson Method. The curves pertaining to the circular ring load versus the deflection at the application point of the ring load and the circular ring load versus the deflection at the apical point of the shell are plotted and compared for various shell radius/thickness ratios and parallel circle radii values.

INTRODUCTION: As indicated by the title, we will discuss Ruga (1) and thin films (2, 3). For “Ruga”, I directly borrowed the opening introduction from previous Journal club “The Ruga mechanics” organized by Dr. Mazen Diab, Dr. Ruike Zhao and Prof. Kyung-Suk Kim. “The ‘ruga’, a Latin term, means a single state of various corrugated material configurations, which form diverse 2D-patterns on solid surfaces, interfaces and in thin films. Typical ruga configurations include large-amplitude wrinkles, creases, folds, ridges, wrinklons, crinkles and crumles.” Thin films are ubiquitous in nature and engineering structures, from nanoscale graphene films to millimeter scale polymer films, from centimeter scale clothes to kilometer space balloon and floating ice sheet (Fig. 1). In this club discussion, we will focus on the intersection between thin films and mechanics of ruga configurations, which definitely is only a subset of the thin film mechanics and ruga mechanics. Further, this discussion is motivated by our recent collaboration on instability of floating thin films with Dr. Joseph Paulsen in Physics department at Syracuse University. Therefore, I will start from the wrinkling, crumpling, and folding in thin films floating on water surfaces and use them as representative examples to explore the nonlinear coupling of gravity, surface tension, curvature, and bending deformation in determining various ruga patterns in general thin film structures.

ABSTRACT: The present paper deals with the buckling of a circular cylindrical shell under axial compression from the viewpoint of energy and the characteristics of deformation. It is shown first, both theoretically and experimentally, that the reason why the buckling of a cylindrical shell is quite different from that of a flat plate is attributable to the existence of a nearly developable surface far apart from the original cylindrical surface. Based upon this result, the experimental fact that the buckling is really not general but local, that is, that the buckled region is limited axially to a range of 1.5 times the wave length of the lobe, is explained by the theoretical result that the minimum buckling load is smaller in the local buckling than in the general buckling case.

ABSTRACT: The applications of membranes are increasing rapidly in various fields of engineering and science. The geometric, material, force and contact non-linearities complicate their analysis, which increases the demand for computationally efficient methods and interpretation of counter-intuitive behaviours. To understand the complex behaviour of membrane structures, it is necessary to perform parametric studies of simple setups and understand their basic mechanical behaviour.

The first part of the present work studies the free and constrained inflation of circular and cylindrical membranes. The membranes are assumed to be in contact with a soft substrate, modelled as a linear spring distribution. Adhesive and frictionless contact conditions are considered during inflation, while only adhesive contact conditions are considered during deflation. For a circular membrane, peeling of the membrane during deflation is studied, and a numerical formulation of the energy release rate is proposed. The pre-stretch produces a stiffening effect for the circular membranes, and a softening effect for the cylindrical membranes, in the pre-limit zone.

The second part of the thesis discusses the instabilities observed for fluid containing cylindrical membranes. Limit points and bifurcation points are observed on primary equilibrium branches. The secondary branches emerge from bifurcation points, with their directions determined by eigenvectors corresponding to zero eigenvalues at the bifurcation point. Symmetry has major implications on stability analysis of the structures, and the relationship between eigenvalue analysis and symmetry is highlighted in this part of the thesis. The occurrence of critical points and the stability of equilibrium branches are determined by perturbation techniques. In the third part, wrinkling in the pressurized membranes is investigated, and robustness of the modified membrane theory and tension field theory is examined. The effect of boundary conditions, thickness variations, and inflating media on the wrinkling is investigated. It is observed that, with a relaxed strain energy formulation, the obtained equilibrium solutions are unstable due to the occurrence of pressure induced instabilities. These instabilities are not visible when axisymmetry is assumed or coarse discretizations in the wrinkling direction are used. A detailed analysis of pressure induced instabilities in the wrinkled membranes is described in the thesis.

ABSTRACT: Modelling of structural instability problems is considered for thin square membranes subjected to hydrostatic pressure, with a focus on the effects from symmetry conditions considered or neglected in the model. An analysis is performed through group-theoretical concepts of the symmetry aspects present in a flat membrane with one-sided pressure loading. The response of the membrane is described by its inherent differential eigensolutions, which are shown to be of five different types with respect to symmetry. A discussion is given on how boundary conditions must be introduced in order to catch all types of eigensolutions when modelling only a subdomain of the whole. Lacking symmetry in a FEM model of the whole domain is seen as a perturbation to the problem, and is shown to affect the calculated instability response, hiding or modifying instability modes. Numerical simulations verify and illustrate the analytical results, and further show the convergence with mesh fineness of different aspects of instability results.

ABSTRACT: This paper discusses the evaluation of instabilities on the quasi-static equilibrium path of fluid-loaded pre-stretched cylindrical membranes and the switching to a secondary branch at a bifurcation point. The membrane is represented by only the in-plane stress components, for which an incompressible, isotropic hyperelastic material model is assumed. The free inflation problem yields governing equations and boundary conditions, which are discretized by finite differences and solved by a Newton–Raphson method. An incremental arclength-cubic extrapolation method is used to find generalized equilibrium paths, with different parametrizations. Limit points and bifurcation points are observed on the equilibrium path when fluid level is seen as the controlling parameter. An eigen-mode injection method is employed to switch to a secondary equilibrium branch at the bifurcation point. A limit point with respect to fluid level is observed for a partially filled membrane when the aspect ratio (length/radius) is high, whereas for smaller aspect ratios, the limit point
with respect to fluid level is observed at over-filling. Pre-stretch is observed to have a stiffening effect in the pre-limit zone and a softening effect in the post-limit zone.

always accompanied by buckling distortions where fusion welding is applied. Buckling distortions are more

ABSTRACT: Curie symmetry principle, the causality relation between the symmetry of the causes and the resultant effect, has often been invoked to infer the composite deformation history of geological bodies in the Earth’s crust. This principle provides a powerful constraint for predicting an unavailable past physical condition; the effects at the macroscopic level must be the same or higher symmetry than the intersection of the causes. However, in nonlinear phenomena, it is shown that the resultant effect selects a lower symmetry than the intersection of causes, which logically opposes the principle. Here, we introduce a symmetry breaking principle where the symmetry group of the effect is included in the intersection of the causes, and derive a new nonlinear phenomenological equation to formulate the symmetry breaking phenomena. The new principle suggests that the anisotropic pattern may not be necessary to consider the anisotropic causes or the multiple deformation history under nonlinear phenomena.

ABSTRACT: This chapter presents that manufacturing of sheet-metal-formed plates, panels, and shells are always accompanied by buckling distortions where fusion welding is applied. Buckling distortions are more
marked than other forms of welding distortions in thin-walled structural elements and they are the main troublesome problems in sheet metal fabrication. Recent progress in mathematical modeling and numerical simulation of welding phenomena offers researchers powerful tools for studying in more detail three-dimensional welding thermal and mechanical behaviors. Investigations in the field of innovative creation of new methods for welding distortion especially to prevent buckling are the world's most exciting and challenging subjects, involving many disciplines and industrial practice and process experiments. Those tools allow for the prediction of precise control of the abnormal temperature fields and therefore the abnormal thermal elastic-plastic cycles created by the possible combinations of the heat source–heat sink: multiple-source welding techniques. It is expected that a variety of coupled heat source–heat sink processes are feasible not only to control welding distortion, but also to produce defect-free specimens.

ABSTRACT: The industry in the fields of civil and mechanical engineering, and in particular of aerospace demands for significantly reduced development and operating costs. Reduction of structural weight at safe design is one avenue to achieve this objective. The running ESA (European Space Agency) study Probabilistic Aspects of Buckling Knock Down Factors – Tests and Analyses contributes to this goal by striving for an improved buckling knock-down factor (the ratio of buckling loads of imperfect and perfect structures) for unstiffened CFRP (carbon fiber reinforce plastics) cylindrical shells, and by validation of the linear and non-linear buckling simulations based on test results. DLR is acting as study contractor. The paper presents an overview about the DLR buckling tests, the measurement setup and the buckling simulations which are done so far, and gives an outlook to the results which are expected until the end of the running project.

ABSTRACT: A test method is described to experimentally investigate curved stiffened composite panels with respect to their buckling and post-buckling behavior up to collapse. The test method utilizes a new test rig with which stringer and frame stiffened curved panels can be tested under uniaxial compression loads, in-plane shear loads as well as a combination of both. During shear loading the panel is guided according to its radius. The whole test rig can be adjusted to cover a large range of geometric shell parameters. Results will be presented for

different stiffened composite panel designs. Effects of the chosen load introduction and the boundary conditions will be discussed, which have a considerable influence on the panel behavior. In addition, procedures and measurement techniques used during the tests will be explained. The findings confirm that the test method and in particular the new test rig is suitable to investigate representative stiffened structures under in-plane loading conditions relevant for stability analysis.

ABSTRACT: Statistical properties and phase transitions of semiflexible polymers on a soft elastic shell are investigated by using a molecular dynamics (MD) simulation method. The phase diagram of adsorbed semiflexible polymers depends on the bending energy of the elastic shell and the binding energy between polymers and the elastic shell. The ordered regular pentagons of polymers are observed at a moderate adhesive strength and bending energy. At the same time, the shape of the soft elastic shell can be controlled easily by adjusting the chain length of adsorbed polymers, which is helpful for the regulation and reshaping of membranes in the micrometre range or smaller sizes.

“Study on Elastic Global Shear Buckling of Curved Girders with Corrugated Steel Webs: Theoretical Analysis and FE Modelling”, Applied Sciences, Vol. 8, 2457, DOI: 10.3390/app8122457

ABSTRACT: Despite the construction of several curved prestressed concrete girder bridges with corrugated steel webs (CSWs) around the world, their shear behavior has seldom been investigated. Accordingly, this paper substitutes the lack of available information on the global elastic shear buckling of a plane curved corrugated steel web (PCCSW) in a curved girder. This is based on the equilibrium equations and geometric equations in the elastic theory of classical shells, combined with the constitutive relation of orthotropic shells. Currently, the global elastic shear buckling process of the PCCSW in a curved girder is studied, for the first time in literature, with an equivalent orthotropic open circular cylindrical shell (OOCCS) model. The governing differential equation of global elastic shear buckling of the PCCSW, as well as its buckling strength, is derived by considering the orthotropic characteristics of a corrugated steel web, the rational trigonometric displacement modes, Galerkin’s method and variational principles. Additionally, the accuracy of the proposed theoretical formula is verified by comparison with finite element (FE) results. Moreover, the expressions of the inner or outer folded angle and radius of curvature are given by the cosine theorem of the trigonometric function and inverse trigonometric function. Subsequently, parametric analysis of the shear buckling behavior of the PCCSW is carried out by considering the cases where the radius of curvature is constant or variable. This parametric analysis highlights the effects of web dimensions, height-to-thickness ratio, aspect ratios of longitudinal and inclined panels, corrugation height, curvature radius and folded angles on the elastic shear buckling strength. As a result, this study provides a theoretical reference for the design and application of composite curved girders with CSWs.

ABSTRACT: By expanding the response of a cylindrical shell in truncated Fourier series, the nonlinear Donnell type shell equations for imperfect stiffened shells were reduced to a set of linear equations in the correction terms by Newton's method of quasilinearization. Solutions were obtained for isotropic and for ring and stringer stiffened shells. The amplitudes of the initial imperfections used in the analysis were calculated from the corresponding Imbert-Donnell imperfection models. The free parameters in this imperfection model were
obtained by least square fitting the harmonics of the experimentally measured initial imperfections. It was possible in all cases to achieve satisfactory correlation using only a few suitably chosen deflection and imperfection modes.

ABSTRACT: An outline of methods for the analysis of elliptic and hyperbolic shell. roofs is given, incorporating brief descriptions of the membrane and bending theories, methods of solution of the governing differential equations, and experimental studies of model shells.

ABSTRACT: An experimental program to determine the response of thin-walled steel projectiles to the impact with concrete targets was recently conducted. The projectiles were fired against41-MPa concrete targets at an impact velocity of 290 m/s. This article contains an outline of the experimental program, an examination of the results of a typical test, and predictions of projectile deformation by classical shell theory and computational simulation. Classical shell analysis of the projectile indicated that the predicted impact loads would result in circumferential buckling. A computational simulation of a test was conducted with an impact/penetration model created by linking a rigid-body penetration trajectory code with a general-purpose finite element code. Scientific visualization of the resulting data revealed that circumferential buckling was induced by the impact conditions considered.

BACKGROUND: Investigations into the survivability of hardened structures due to impact by conventional air-delivered munitions such as air-delivered bombs, have focused on defeating the bomb by casing failure. A traditional method of hardening structures against attack by aerial bombs is to place a burster slab over the structure. The burster slab is designed to detonate or break up contact-fused bombs and withstand penetration and blast effect of tail-fused bombs (Department of the Army, 1986). A concrete burster slab design was recently evaluated to investigate the effect of construction joints on the penetration resistance of the slab. Subscale thin-walled projectiles (simulating general purpose bombs) were fired into sections of the burster slab within a velocity range of 276-298 m/s. The penetration experiments were conducted at the US Army Engineer Waterways Experiment Station (WES) Projectile Penetration Research Facility which accommodates large targets constructed under laboratory-controlled conditions (Frew et al., 1993). All projectiles broke up after partial penetration into the slab. This article presents a discussion of the test results, an analysis of the structural response of the projectile using classical shell theory, and an ABAQUS finite element simulation of the test (ABAQUS is available under license from Hibbitt, Karlsson, and Sorensen, Inc., 1989a,1989b, 1989c).

“BMP”= “Bone Morphogenetic Proteins”
SIGNIFICANCE: During embryogenesis, the dramatic transformation from a seemingly disorganized mass of cells into the fully patterned adult form necessitates stereotyped regulation of forces at the genetic and molecular level. Although great progress has been made in understanding how gene expression and signaling generate biological pattern, little is known about how molecular cues organize forces to sculpt physical patterns during development. The present work identifies BMP signaling as a key pathway in controlling looping of the small intestine, a process driven by mechanical buckling due to elongation of the intestine against the constraint of a neighboring tissue, the dorsal mesentery.

ABSTRACT: Looping of the initially straight embryonic gut tube is an essential aspect of intestinal morphogenesis, permitting proper placement of the lengthy small intestine within the confines of the body cavity. The formation of intestinal loops is highly stereotyped within a given species and results from differential-growth–driven mechanical buckling of the gut tube as it elongates against the constraint of a thin, elastic membranous tissue, the dorsal mesentery. Although the physics of this process has been studied, the underlying biology has not. Here, we show that BMP signaling plays a critical role in looping morphogenesis of the avian small intestine. We first exploited differences between chicken and zebra finch gut morphology to identify the BMP pathway as a promising candidate to regulate differential growth in the gut. Next, focusing on the developing chick small intestine, we determined that Bmp2 expressed in the dorsal mesentery establishes differential elongation rates between the gut tube and mesentery, thereby regulating the compressive forces that
buckle the gut tube into loops. Consequently, the number and tightness of loops in the chick small intestine can be increased or decreased directly by modulation of BMP activity in the small intestine. In addition to providing insight into the molecular mechanisms underlying intestinal development, our findings provide an example of how biochemical signals act on tissue-level mechanics to drive organogenesis, and suggest a possible mechanism by which they can be modulated to achieve distinct morphologies through evolution.

INTRODUCTION: Differential growth represents one of the core physical mechanisms driving morphogenesis throughout the vertebrate embryo. Investigations into the mechanics of differential growth have often illustrated key physical parameters (e.g., tissue stiffness, growth rates, and initial geometry) that determine the resultant tissue shape. Ultimately, however, these parameters must be under genetic control. However, at present, there are only a limited few examples of how developmental signals are integrated with downstream physical properties to shape the embryo. Here, we build on our detailed understanding of the physics of loop morphogenesis in the chick small intestine (1) to ask what molecular cues underlie this important physical transformation during gastrointestinal development.

Looping maximizes the absorptive capacity of the gut by allowing intestinal length to extend well beyond the linear length of the organism, while maintaining an ordered configuration in the body cavity. Errors in looping, such as malrotation of the gut, can result in obstruction of the bowel or strangulation of the abdominal circulation, a condition known as midgut volvulus (10). Among birth defects, intestinal malrotation is relatively common in newborns and can be fatal if left untreated (11, 12). Early during looping morphogenesis, the initially straight midgut forms a primary loop that extends into the yolk stalk (umbilicus in mammals). Subsequent loops continue to form outside the body cavity as the midgut elongates, until the looped intestine retracts into the body cavity before birth. Although the intestine continues to elongate, no further loops form after birth. The number and shape of intestinal loops are remarkably conserved within a given species (1, 10). In previous work, we demonstrated that this precisely stereotyped looping results from physical forces that arise due to elongation of the initially straight gut tube against the constraint of the dorsal mesentery, a thin membranous tissue that anchors the gut tube to the body wall (1). As the gut tube elongates, it stretches the mesentery, which in turn compresses the tube. As a result of these compressive forces, the gut tube buckles into a looped configuration. The curvature and wavelength of loops can be mathematically predicted from experimentally measured parameters describing geometry and stiffness of the tube and mesentery, and differential elongation between the two tissues (1). Equipped with an understanding of the physics involved, here we aim to elucidate the underlying signaling pathways that control intestinal looping in the chicken embryo.

ABSTRACT: More adaptable geometric form of offshore platforms, counting on the benefits of form-dominant design, is effective to encounter various environmental loads. Offshore triceratops is a new-generation offshore platform, whose conceptual design showed good degree-of-adaptability to ultra-deep-water conditions. Deck is partially isolated from the buoyant legs by ball joints by allowing transfer of partial displacements of buoyant legs to deck but restraining transfer of rotational responses. Prior to the suitability assessment of triceratops for ultra-deep waters, detailed dynamic analysis on the preliminary geometric form is necessary as a proof of validation for design applications. Current study discusses a detailed numeric analysis of triceratops at 2400 m water depth under regular and irregular waves; preliminary design of both buoyant legs and the deck is also presented. Buoyant Legs are designed as stiffened cylinders and the deck is designed as the integrated truss system. In compliant structures, the role of tethers is of paramount importance. Hence, the stress analysis and fatigue analysis of the tethers are also carried out to assess the service life of the structure. Presented study shall aid offshore engineers and contractors to understand suitability of triceratops, in terms of design and dynamic response behaviour.

ABSTRACT: Considering the effect of stress wave, the dynamic buckling of circular cylindrical shells under an axial step load is discussed using the classical shell theories and the state-space technique in the paper. Based on the Hamilton’s principle, the dynamic buckling governing equations of shells are derived and solved with the Rayleigh-Ritz method. If the linear homogeneous equations have a non-trivial solution, the determinant of the coefficient matrix must be equal to zero, so the expression of the critical load on the dynamic buckling is got. The relationship between the critical load and length is obtained by using MATLAB software. The influences of boundary conditions, thickness, the number of circumferential waves and the number of axial waves on the dynamic buckling loads are discussed based on numerical computation.

ABSTRACT: Shape optimization design is carried out in the paper aiming at the feature of openings on curved shells to enhance the structural stability and reduce the stress concentration. In order to make sure that the hole boundary curve are always located on the prescribed curved shell, the parametrical mapping method is employed to describe the hole boundary on the curved shells with shape design variables defined in the intrinsic reference domain. Then, different optimization models are established and the specific sensitivity is calculated for buckling optimization. Finally, it concludes from numerical examples that the structural stability and the
ABSTRACT: The instability of the testing equipment protective shell is one of the importance issues in the design of testing equipment. In order to analyze the protective shell to external shocks instability problem, the shell instability of empirical formula was used to calculate the critical buckling load and the linear buckling was analysed to compare the simulation results with theoretical values and the error in control range by using finite element method. The calculations show that the finite element method for buckling analysis to provide guidance for the design is feasible.

ABSTRACT: Often the parameters considered as constants in an optimization problem have some uncertainty and it is interesting to know how the optimum solution is modified when these values are changed. The only way to continue having the optimal solution is to perform a new optimization loop, but this may require a high computational effort if the optimization problem is large. However, there are several procedures to obtain the new optimal design, based on getting the sensitivities of design variables and objective function with respect to a fixed parameter. Most of these methods require obtaining second derivatives which has a significant computational cost. This paper uses the feasible direction-based technique updating the active constraints to obtain the approximate optimum design. This procedure only requires the first derivatives and it is noted that the updating set of active constraints improves the result, making possible a greater fixed parameter variation. This methodology is applied to an example of very common structural optimization problems in technical literature and to a real aircraft structure.

ABSTRACT: Aortic dissection (AD) is a serious medical condition characterized by a tear in the intima, the inner layer of the aortic walls. In such occurrence, blood is being diverted to the media (middle) layer and may result in patient death if not quickly attended. In the case where the diseased portion of the aorta needs to be replaced, one common surgical technique is to use a graft made of Dacron, a synthetic fabric. We investigate the response of a composite human aortic segment-Dacron graft structure subjected to blood flow using the three-dimensional fluid-structure-interaction (FSI) capability in Abaqus. We obtain stress and strain profiles in each of the three layers of the aortic walls as well as in the Dacron graft. Results are compared when elastic and hyperelastic models are used and when isotropy vs. anisotropy is assumed. The more complex case
(hyperelastic-anisotropy) is represented by the Holzapfel-Gasser-Ogden (HGO) model which also accounts for the orientation of the fibers present in the tissues. The fluid flow is taken as Newtonian, incompressible, pulsatile and turbulent. The simulation show that for all the cases, the von Mises stress distribution at aorta-Dacron interface is well below the ultimate strength of the aorta. No significant change in radial displacement at the interface of the two materials due to blood flow is observed. Computation cost is also addressed and results show that the hyperelastic-anisotropic model takes about three times longer to run than the elastic isotropic case. Trade-off between accuracy and computational cost has to be weighted.

ABSTRACT: The effect of pre-buckling nonlinearity on the bifurcation point of a conical shell is examined on the basis of three shell theories: Donnell’s, Sanders’ and Timoshenko’s. The eigenvalue problem is solved iteratively about the nonlinear equilibrium state up to the bifurcation point. A new algorithm is presented for the real buckling behavior, dispensing with the need to cover the entire nonlinear pattern. This algorithm is very important for structures characterized by a softening process, in which the pre-buckling nonlinearity depresses the buckling level relative to the classical one. The procedure involves nonlinear partial differential equations, which are separated into two sets (using the perturbation technique) for the pre-buckling and buckling states, respectively and solved with the variable expanded in Fourier series in the circumferential direction, and by finite differences in the axial direction. A general computer code was developed and used in studying the effect of the pre-buckling nonlinearity on the buckling level, of the shell under axial compression, in the context of the three shell theories.

Advanced School on Global Nonlinear Dynamics for Engineering Design and System Safety (Udine, 13–17 June, 2016). Lectures to be published by CISM and Springer

ABSTRACT: During the explosion of interest in applied nonlinear dynamics and chaos in the 1980s a key concept was quickly seen to be the concept of dynamically integrity which was required to cope with, for example, the erosion of basins of attraction by fractal incursions. Articles by Thompson and Soliman laid down the fundamentals ideas, but major contributions by Rega and Lenci established this integrity as a central issue in the design of (for example) structures in their inevitable dynamic environment. They extended and developed the various integrity measures and pioneered ways of controlling the basin erosion phenomenon: and applied the ideas to a wide range of mechanical problems. The present paper offers a review of this progress, highlighting key conceptual ideas and some of the more interesting applications.

ABSTRACT: Not only the geometrical imperfection induced by welding but also cutouts will influence the buckling of large-scale thin-walled steel cylindrical shell under wind loading. Based on the practical cylindrical shells of a desulphurizing absorption tower, in consideration of the correlation between welding induced imperfection and circular cutouts, the influence of cutout position on buckling of cylinder under wind loading is investigated by nonlinear finite element method. The results indicate that the buckling capacity varies slightly when the cutout position moves along meridional direction in the neighboring region of welding imperfection. The buckling capacity varies significantly when the cutout position moves circumferentially as the cutout is located in the welding imperfection. The buckling capacity reaches the minimum value as the cutout is located in the buckle center of cylindrical shells without cutout.

ABSTRACT: We report that a graphene sheet has an unusual mode of atomic-scale fracture owing to its structural peculiarity, i.e. single sheet of atoms. Unlike conventional bond-breaking tensile fracture, a graphene sheet can be cut by in-plane compression, which is able to eject a row of atoms out-of-plane. Our scale-bridging
molecular dynamics simulations and experiments reveal that this compressive atomic-sheet fracture is the critical precursor mechanism of cutting single-walled carbon nanotubes (SWCNTs) by sonication. The atomic-sheet fracture typically occurs within 200fs during the dynamic axial buckling of a SWCNT; the nanotube is loaded by local nanoscale flow drag of water molecules caused by the collapse of a microbubble during sonication. This is on the contrary to common speculations that the nanotubes would be cut in tension, or by high-temperature chemical reactions in ultrasonication processes. The compressive fracture mechanism clarifies previously unexplainable diameter-dependent cutting of the SWCNTs under sonication.

ABSTRACT: The buckling of an orthotropic composite cylindrical shell with variable thickness, subjected to a dynamic loading, is reported here. At first, the fundamental relations and Donnell type dynamic buckling equation of an orthotropic cylindrical shell with variable thickness have been obtained. Then, employing Galerkin’s method, these equations have been reduced to a time dependent differential equation with variable coefficients. Finally, for different initial conditions and approximation functions, applying the Ritz type variational method, analytical expression has been found for the dynamic factor. Using these results, the effect of the variations of the power of time in the external pressure expression, the loading parameter and the ratios of the Young’s moduli on the dynamic factor are studied numerically for the case when the thickness of the cylindrical shell varies as a power and exponential functions. It has been observed that these effects change the dynamic factor of the problem in the heading appreciably.

ABSTRACT: This paper present an investigation of the collapse load in cylinder shell under uniform external hydrostatic pressure with optimum design using finite element method via ANSYS software. Twenty cases are studied inclusive stiffeners in longitudinal and ring stiffeners. Buckling mode shape is evaluated. This paper studied the optimum design generated by ANSYS for thick cylinder with external hydrostatic pressure. The primary goal of this paper was to identify the improvement in the design of cylindrical shell under hydrostatic pressure with and without Stiffeners (longitudinal and ring) with incorporative technique of an optimization into ANSYS software. The design elements in this research was: critical load, design variable (thickness of shell (TH), stiffener’s width (B) and stiffener’s height (HF)). The results obtained illustrated that the objective is minimized using technique of numerical optimization in ANSYS with optimum shell thickness and stiffener’s sizes. In all cases the design variables (thickness of shell) was thicker than the monocoque due to a shell’s thicker is essential to achieve the strength constraints. It can be
concluded that cases (17,18,19, and 20) have more than 90% of un-stiffened critical load. The ring stiffeners causes increasing buckling load than un-stiffened and longitudinal stiffened cylinder.

ABSTRACT: Non-destructive methods to estimate the actual buckling load in particularly for imperfection sensitive thin-walled structures, are of severe interest among many fields. Particular techniques for validation of structural limit state and numerical model predictions for large scale structures are getting momentum. The vibration correlation technique (VCT) allows to correlate the ultimate load our instability point with rapid decrement of self-frequency response. Nevertheless this technique is still under development for thin-walled shells and plates. The current research discusses an experimental verification of extended approach, using vibration correlation technique, for the prediction of actual buckling loads on unstiffened cylindrical shells loaded in axial compression. Validation study include two laminated composite cylinders which were manufactured and repeatedly loaded up to instability point. In order to characterize a correlation with the applied load, several initial natural frequencies and mode shapes were measured during tests by 3D laser scanner. Results demonstrate that proposed vibration correlation technique allows one to predict the experimental buckling load with high reliability, without actually reaching the instability point. Additional experimental tests and numerical models are currently under development to further validate the proposed approach to extended composite and metallic structures.

ABSTRACT: Even though the thermal buckling behavior of shells has been investigated for many years, until now the thermal buckling problem with temperature-dependent material properties still cannot be solved by the existing commercial finite element codes. Therefore, the conventional theoretical solution of the critical temperature rise of cylindrical shell with temperature-dependent material properties is first derived in this work. Then, an innovative numerical approach is developed by introducing the bisection method and a user subroutine of ANSYS to overcome the shortcoming of existing finite element codes. The results prove that the temperature-dependent material properties have a great negative influence on the ability of the thermal buckling resistance of the cylindrical shell. As a result, the subroutine of ANSYS developed in this work provides a convenient design method for engineers to avoid the complicated theoretical calculation.

Michael Rotter (The University of Edinburgh), “Stability of column-supported steel cylinders with engaged columns”, Proceedings of the International Association for Shell and Spatial Structures (IASS) Symposium 2009, Valencia; Evolution and Trends in Design, Analysis and Construction of Shell and Spatial Structures 28 September – 2 October 2009, Universidad Politecnica de Valencia, Spain [Alberto Domingo and Carlos Lazaro (editors.)]
ABSTRACT: Steel silos are often supported on a small number of columns to facilitate emptying operations. The connection between these columns and an elevated cylindrical metal silo shell is a long-standing difficult problem in shell analysis. The presence of local supports beneath a cylinder leads to stress concentrations in the cylindrical wall just above the supports, which can cause buckling or plastic collapse and consequently failure of the entire structure. Engaged columns produce a gentler introduction of the support forces into the cylindrical shell and cause a smoother stress distribution above the column termination. Engaged columns are therefore a very practical solution for local supports. In practice, smaller silo structures are often supported on engaged columns attached to the side of the shell, but very few investigations of the structural behaviour or the strength of such an arrangement have ever been made. In this paper, the structural behaviour of a cylinder supported on engaged columns is investigated, including the effects of geometric imperfections and geometric nonlinearity. The study is conducted using the requirements for computational evaluations set out in EN 1993-1-6 (2007) and using the finite element package ABAQUS. The columns are assumed to be flexurally and axially rigid to provide a clear scientific study of the failure behaviour of the cylinder under these conditions.

ABSTRACT: Advanced lightweight laminated composite shells are increasingly being introduced in designs of modern aerospace structures, for enhancing their structural efficiency and performance. They are susceptible to buckling when subjected to significant static and dynamic or time dependent loadings. Their strength as governed by buckling is affected by initial geometric imperfections, boundary conditions, lamina stacking sequence and load eccentricity. While numerous studies are available on the buckling and post buckling behaviour of isotropic shells and the effects of geometric imperfections, relatively few investigations have been undertaken on the laminated composite shells for dynamic loading conditions. The need to design shell structures that have to withstand time-dependent dynamic loads, sometimes quite severe, and thus may be susceptible to dynamic buckling is relatively new in aerospace structures. The term dynamic buckling refers to two different phenomena. One is associated with the response of the structure to the action of cyclic loads i.e.
vibration buckling, and the second one relates to the behaviour of structures subjected to pulse loads. The presence of imperfections may also adversely affect the buckling behaviour of the shells. This paper deals with a numerical study on the effect of different shell parameters and imperfections on the buckling behaviour of circular cylindrical composite shells under axial impact. Composite cylindrical shells with three different layups $[0^\circ/0^\circ/60^\circ/60^\circ]_S$, $[0^\circ/45^\circ/-45^\circ/0^\circ]_S$ and $[75^\circ/-75^\circ/75^\circ/-75^\circ]_S$, each having different length to radius ratios (L/R) and radius to thickness ratios (R/t) have been considered in this study.

ABSTRACT: This chapter is devoted to the stability behavior of thin cylindrical shells. The basic governing equations of thin circular cylindrical shells employing the Donnell theory with the von-Karman geometrical non-linearity are derived. The nonlinear strain-displacement relations, the nonlinear equilibrium equations, and the linear stability equations are derived employing the variational formulations. The cylindrical shell under uniform compressive axial load is considered and the buckling load is obtained and given by closed form solution. Thermal buckling of cylindrical shell made of FGM for the uniform temperature rise, linear radial temperature, and the nonlinear radial temperature are presented and the effect of piezo-control is examined. Buckling and postbuckling of thin cylindrical shells with piezo-control under thermal loads is discussed and the chapter concludes with the stability discussion of cylindrical shells on elastic foundation. The buckling loads of
cylindrical shells of isotropic/homogeneous material are derived by simply setting proper values for the power law index of the FG materials.

Critical buckling load of a cylindrical shell having an elliptical cut-out orientation had a positive influence in which the buckling load value increased too. For this reason, an increase in the buckling load value. Moreover, the study showed that increasing parameters such as shell thickness and cut-out location from mid-height of the cylindrical shell towards a fixed edge caused increase in the buckling load value. Moreover, the study showed that increasing parameters such as shell thickness and cut-out orientation have a positive influence in which the buckling load value increased too. For fast design purposes, an empirical numerical based regression formula was presented for the calculation of the critical buckling load of a cylindrical shell having an elliptical cut-out.

PARTIAL INTRODUCTION: The experimental setup is rudimentary. Pick up a piece of a spongy sleeve, of the kind commonly used to fit over water pipes for insulation. You need a stub about one meter long, which is useless stuff for pipe installers, so you can easily get it for free. Hold the tube at both ends with your hands and twist energetically while pulling apart. If the tube is soft enough, you will be able to give several turns before it coils up, as shown in Figure 2. We expect you to observe the pattern of Figure 1, as long as you succeed in keeping the axis of the tube straight: its cross sections, circular when unstressed, flatten into a quasi-oval form, whose aspect ratio is essentially constant along the tube and increases with twist in a markedly nonlinear way; the principal axes of the oval seem to whorl at a uniform rate dictated by the twist (the parameter your hands control). This pattern is quite insensitive to the way you grab and squeeze each end of the tube, provided you apply suitable end torques and forces. In this paper, we aim at the simplest rational model that reproduces and explains this behaviour.

ABSTRACT: Major advances in the buckling analysis of cylindrical shells have been achieved in the last two decades. Eurocode nowadays provides rules for tanks up to r/t = 5000. However, since only few literature has become available in the past, dealing specifically with very thin walled shells in the range between r/t = 1500 and r/t = 10000, code provisions either are quite conservative or, in case of r/t > 5000, do barely exist. Employing modern construction methods, close-to-perfect, very thin-walled shells can be built that are out of the scope of the design codes. Therefore, to achieve more economical designs and a better sustainability, sophisticated design tools have to be used.

In this paper, modifications and extensions of the current design procedure are proposed to overcome current limitations and drawbacks. A review of experiments with a special focus on cylinders with high r/t-ratios was conducted and modified lower bound approximation curves for the knock-down factor α deduced. They were checked against representative experiments from literature. Test results recalculated using an axisymmetric imperfection to explore their equivalent imperfection depth, proved that even small imperfections drastically reduce the buckling strength. Using a parametric study, the result range of α was extended up to r/t = 10000. The design proposal could be approved and an equation for the determination of an equivalent imperfection depth that relates the dependence of α to the imperfection depth and the r/t-ratio is proposed.

Simos Gerasimidis and Pedro Reis, “Shell Buckling”, date and publisher not given in the pdf file

ABSTRACT: The arena of shell buckling received great attention after the monumental development of a general theory on elastic buckling and post-buckling behavior by Koiter in 1945. For more than three decades, the literature on shell buckling flourished with investigations on imperfections sensitivity, minimum buckling loads and instability modes. Following this intense progress, the field entered a period of idleness, up until very recently. Today, 74 years after Koiter’s presentation, there is a strong resurgence of activity in studying the mechanics of shell buckling which is observed worldwide by numerous research efforts. With the rapid progress in new materials and computational and experimental technology, a breadth of exciting new ideas has revitalized the problem. This mini-symposium will provide a forum for discussing the most recent computational, theoretical and experimental findings in the area of shell buckling, as well as future research directions.

ABSTRACT: Purpose: The aim of the paper is to evaluate buckling instabilities behaviour of long curved thin shell. Both initially straight and curved tubes are investigated with numerical and experimental assessment methods, in the context of NPP applications with an illustrative example for IRIS LWR integrated Steam Generator (SG) tubes. Design/methodology/approach: In this study structural buckling response tube with combination effects of geometric imperfections as well as initially bent shape under external pressure load are investigated using a non linear finite element (MSC.MARC FEM code) formulation analysis. Moreover results are presented, extending the findings of previous research activity works, carried out at Pisa University, on thin walled metal specimen. Findings: The experiments were conducted on Inconel 690 test specimen tube. The comparison between numerical and experimental results, for the same geometry and loading conditions, shows a good agreement between the elastic-plastic finite-element predictions and the experimental data.

Research limitations/implications: The presented research results may be considered preliminary in the sense that it would be important to enlarge the statistical base of the results themselves, even if they are yet certainly meaningful to highlight the real problem, considering the relatively large variability of the geometrical imperfections and bending instabilities also in high quality production tubes.

Originality/value: From the point of view of the practical implication, besides the addressed problem general interest in industrial plant technology, it is worth to stress that straight and curved axis tubes are foreseen specifically in innovative nuclear reactors SG design.

INTRODUCTION: The centenary of the publication of Love’s paper ‘The small free vibrations and deformation of a thin elastic shell’ provides us with an opportunity of looking at the subject of shell structures from a long perspective.

Problems arising from the analysis and design of thin shell structures have stimulated urgent research more or less continuously over the last hundred years. In surveying this work we can take two different viewpoints. On the one hand we can concentrate on the manifold changes which have taken place during the period in the industrial fields of application, in experimental methods, in the refinement and development of the basic equations, and in the methods of solution. On the other hand we can consider those aspects of our subject which have changed relatively little over the period under review.

The first of these viewpoints is, of course, the more obvious. For we have seen the fields of application embrace in turn aircraft, submarines, power plant, spacecraft and various aspects of oil production, and extend to parachutes and other membranes; we have witnessed the development of increasingly sophisticated experimental techniques and instrumentation; we have seen the ascendancy of tensor notation; we have seen the development of theory for both geometrical and material non-linearity; and we have seen an almost complete revolution from algebraic to numerical methods of analysis in the past twenty-five years.

Although I shall touch on some aspects of this long procession of advances during this lecture, I have decided to focus attention mainly on some of the unchanging features of our subject. My reasons for taking this second viewpoint are threefold. First, it makes a more manageable subject for a single lecture: to do justice to the many changes that have taken place would require a whole course of lectures and indeed I am inadequate as a scholar for such a task. Second, this perspective helps to provide an answer to the question of how it is that the same kinds of problem have constantly recurred in our subject over the last hundred years, whereas other subjects—such as chemistry and biology—have altered out of all recognition in the same period. And third, it allows me the opportunity to consider at greater length the contribution which Love himself made to our field.

The layout of my lecture is as follows. First I shall sketch the salient points of the life of A.E.H. Love. Then I shall describe in some detail the nature of Love’s work on thin shells, the circumstances in which it came to be done, and the changes which gradually took place in his view of the subject. Next, I shall outline the advances made in the theory over the last hundred years, and describe briefly the present state of the subject. Lastly, I shall discuss various difficulties, as I see them, which were evident one hundred years ago and which survive to the present time.

ABSTRACT: This paper treats in detail the life and work of Otto Blumenthal, one of the most tragic figures of the 188 emigré mathematicians from Germany and the Nazi-occupied continent. Blumenthal, the first doctoral student of David Hilbert, was crucial in the publication and communication system of German mathematics between the two World Wars. There has been an unusual revival of interest in his mathematical work in the last three decades. Thus his work on orthogonal polynomials whose zeros are dense in intervals, called the Blumenthal theorem by T.S. Chihara (1972), lead to over two dozen recent papers in the field. The Blumenthal–Nevai theorem, with applications to scattering theory in physics, is one example. In modern work on Hilbert modular forms, increasingly being called Hilbert–Blumenthal modular forms, many recent papers even contain the word Blumenthal in their titles. This paper contains 212 references.

Addendum relating to the paper by Calladine and the paper about Blumenthal (written by Igor Andrianov)

It should be noticed that a development of mathematical physics in many cases has been motivated by TS problems, in particular we mean those problems associated asymptotical methods (AM). Recall, that a key (for singular asymptotics) concept of an edge effect occurred in the works of H. Lamb and A B. Basset in 1890, while concept of boundary layer occurred in Fluid Mechanics only in 1904 [1].
The classical papers by M.I. Vishik and L.A. Lyusternik are generalization of some results obtained earlier by A.L. Gol’denberg. On the other hand, TS problems associated with occurrence of high technology development of materials and constructions implied development of various homogenization procedures. Investigation of rods stability by Euler yielded a linearization procedure, whereas W.T. Koiter approach has strongly influenced an occurrence of today’s Catastrophe Theory.

Bolotin V.V. mentioned WKB OR BLUMENTHAL -SHTAERMAN APPROACH. Really, in Math Congress paper 1912 [2] BLUMENTHAL used method WKB … which proposed in quantum mechanics in 1926! (Šhtaerman used it in 1924).

Experimental investigation on buckling of cylindrical shell under compression and transverse shear, Sadhana, vol. 29, 2004, Feb., 93-115

ABSTRACT: This paper presents experimental studies on buckling of cylindrical shell models under axial and transverse shear loads. Tests are carried out using an experimental facility specially designed, fabricated and installed, with provision for in-situ measurement of the initial geometric imperfections. The shell models are made by rolling and seam welding process and hence are expected to have imperfections more or less of a kind similar to that of real shell structures. The present work thus differs from most of the earlier investigations. The measured maximum imperfections $\delta_{\text{max}}$ are of the order of plus or minus 3t ($t =$ thickness). The buckling loads obtained experimentally are compared with the numerical buckling values obtained through finite element method (FEM). In the case of axial buckling, the imperfect geometry is obtained in four ways and in the case of transverse shear buckling, the FE modelling of imperfect geometry is done in two ways. The initial geometric imperfections affect the load carrying capacity. The load reduction is considerable in the case of axial compression and is marginal in the case of transverse shear buckling. Comparisons between experimental buckling loads under axial compression, reveal that the extent of imperfection, rather than its maximum value, in a specimen influences the failure load. Buckling tests under transverse shear are conducted with and without axial constraints. While differences in experimental loads are seen to exist between the two conditions, the numerical values are almost equal. The buckling modes are different, and the experimentally observed and numerically predicted values are in complete disagreement.

ABSTRACT: A review of the literature reveals that information regarding fundamental frequencies and mode shapes of shallow laminated composite hypar shells with practical civil engineering boundary conditions is not available. The present investigation aims to fill this gap by applying an eight-noded isoparametric shell element as the tool. Numerical experiments are carried out for different parametric variations including boundary conditions and stacking orders to obtain the fundamental frequencies and mode shapes. Some of the results are used for validating the correctness of the present approach by comparing with the existing benchmark, while the other results are studied meticulously to extract a set of meaningful conclusions regarding the free vibration characteristics of composite shallow hypar shells.

ABSTRACT: Current research issues in the development of efficient analysis models and their efficient numerical implementation for smart piezoelectric laminated structures are discussed in this paper. The improved zigzag theories with a layerwise quadratic variation of electric potential have emerged as the best compromise between accuracy and cost for hybrid composite, sandwich and FGM beams and plates. The concept of associating surface potentials to electric nodes and internal potentials to physical nodes is very effective in modeling the equipotential electroded surfaces. Unified formulations for shear and extension mode actuation, and modeling of piezoelectric composite actuators and sensors are discussed. Future challenge lies in developing efficient theories capable of predicting the interlaminar transverse shear stresses in hybrid laminates directly from the constitutive equations.

Ilinca Stanciulescu (2005), Nonlinear finite element formulations and bifurcation analysis for structures undergoing large deformations, Ph.D. Dissertation, Department of Civil and Environmental Engineering, Duke University.

ABSTRACT: Nonlinear phenomena are common in structural and solid mechanics; in general, the corresponding system of equations cannot be solved analytically, and numerical techniques are necessary. Furthermore, bifurcations of the solution are frequent; they can appear either at the physical level (the system may have multiple equilibrium configurations), or at the numerical level (related to the algorithm utilized in calculating the solution). Unfortunately no algorithm can solve every nonlinear system, and most of the time the recovery of solutions needs alternative iterative techniques. This thesis is concerned with finite element formulations and solution techniques for structures undergoing large deformations. The two applications examined are the steady state frictional rolling of tires and the postbuckling analysis of slender structures.
A formulation for steady state rolling calculations is introduced, focusing on the inclusion of frictional sliding conditions between a rolling tire and a flat roadway. Algorithmically, it is seen that traditional return mapping strategies are often ineffective for this problem even when frictional solutions exist; accordingly, an approach utilizing a global stick predictor is proposed to recover solutions to the sliding contact problem. Numerical examples are presented, to demonstrate the effectiveness of the approach advocated. Difficulties associated with enforcing frictional conditions within such a framework are discussed. The interaction of frictional conditions with bifurcation phenomena is also studied in the case of adherent contact conditions. Such phenomena are observed in the context of multiple solutions of the discretized system, and are also manifested in the behavior of the iterative map used to solve the nonlinear algebraic system of equations.

Another example of bifurcation is the buckling of slender structures with direct application to solar sail booms. An interesting aspect in the boom design is that postbuckled configurations are not avoided as is usually the case in structural design; instead, they are sometimes encouraged. In this context, the understanding of the structural behavior after buckling is essential. Various structural systems and loadings appropriate for the boom modeling are examined here. Natural frequencies of vibration about highly–deflected equilibria are extracted, exposing the high sensitivity that these structures have to minor changes in the geometry and loading.

Wadee, M. A., Yiatsos, S., & Theofanous, M. 2010 (Department of Civil and Environmental Engineering, Imperial College of Science, Technology & Medicine, South Kensington Campus, London SW7 2AZ, UK), “Comparative studies of localized buckling in sandwich struts with different core bending models”, Int. J. Non-Linear Mech., 45(2), 111–120. DOI: 10.1016/j.ijnonlinmech.2009.10.001.

ABSTRACT: Analytical models with geometric nonlinearities accounting for interactions between local and global instability modes leading to localized buckling in sandwich struts are formulated. For the core material response, two increasingly sophisticated bending models are compared against each other: Timoshenko beam theory (TBT) and Reddy–Bickford beam theory (RBT). Numerical solutions of the analytical models are validated with the commercial finite element code Abaqus. It is found that there is a small but significant difference in the critical load between the two models and that the previously obtained solution slightly underestimates the linear buckling strength. More importantly, it is found that the RBT model predicts the onset of interactive buckling before the TBT model and, according to the results from the finite element study, matches the actual behaviour of a strut in both its initial and advanced post-buckling states with excellent correlation.

ABSTRACT: Structural hollow sections are predominantly square, rectangular or circular in profile. While square and circular hollow sections are often the most effective in resisting axial loads, rectangular hollow sections, with greater stiffness about one principal axis than the other, are generally more suitable in bending. Oval or elliptical hollow sections combine the aesthetic external profile of circular hollow sections with the suitability for resisting flexure of rectangular sections, whilst also retaining the inherent torsional stiffness offered by all tubular sections. This paper examines the structural response of recently introduced stainless steel OHS in bending and presents design recommendations. In-plane bending tests in the three-point configuration about both the major and minor axis were conducted. All tested specimens were cold-formed from Grade 1.4401 stainless steel and had an aspect ratio of approximately 1.5. The full moment-rotation responses of the specimens were recorded and have been presented herein. The tests were replicated numerically by means of non-linear FE analysis and parametric studies were performed to investigate the influence of key parameters, such as the aspect ratio and the cross-section slenderness, on the flexural response. Based on both the experimental and numerical results, structural design recommendations for stainless steel OHS in bending in accordance with Eurocode 3: Part 1.4 have been made.

Deployable structures for architectural applications – A short review

ABSTRACT: Deployable structures can provide a change in the geometric morphology of the envelope by contributing to making it adaptable to changing external climate factors, in order to improve the indoor climate performance of the building. They have the ability to transform themselves from a small, closed or stowed configuration to a much larger, open or deployed configuration being also known as erectable, expandable, extendible, developable or unfurlable structures. According to their structural system, deployable structures can be divided into four main groups: spatial bar structures consisting of hinged bars, foldable plate structures consisting of hinged plates, strut-cable (tensegrity) structures and membrane structures. In this paper a short review only on two of these groups of deployable structures for architectural applications will be presented.

ABSTRACT: Aluminum shear panels can dissipate significant amount of energy through hysteresis provided strength deterioration due to buckling is avoided. A detailed experimental study of the inelastic behavior of the full-scale models of shear panels of 6063-O and 1100-O alloys of aluminum is conducted under slow cyclic loading of increasing displacement levels. The geometric parameters that determine buckling of the shear panels, such as web depth-to-thickness ratio, aspect ratio of panels, and number of panels, were varied among the specimens. Test results were used to predict the onset of buckling with proportionality factor f in Gerard’s formulation of inelastic buckling. Moreover, a logarithmic relationship between buckling stress and slenderness ratio of the panel was observed to predict experimental data closely. These relations can be further used to determine the geometry of shear panels, which will limit the inelastic web buckling at design shear strains. (DOI: 10.1115/1.2793135)

Ashwin Kumar and Dipti R. Sahoo (Dept. of Civil Engineering, Indian Institute of Technology Delhi, India), “Effect of brace configurations on the behavior of SCBFS under near-field earthquake”. EUROSTEEL 2014, September 10-12, 2014, Naples, Italy

PARTIAL INTRODUCTION: Special concentrically braced frames (SCBFs) are used as lateral force-resisting systems in steel structures located in the high seismic areas to resist lateral loads through the vertical concentric truss system. Compared to other lateral force resisting systems, this system can be cheaper and is easier to build if proper care is taken in designing and detailing. The braces act as fuses which dissipate the input seismic energy through the tension yielding and compression buckling. Thus, the axial deformation of the braces allows the system as a whole to have ample drift capacity to resist the lateral forces without any failure of gravity load-resisting members. Several parameters, such as, brace slenderness ratio, width-to-thickness ratio, size and detailing of gusset plate, brace configurations, etc. control the response of SCBFs under earthquake loading [e.g., 1-3].

ABSTRACT: Special concentrically braced frames (SCBFs) are commonly used to resist lateral forces in structures located in high-seismic regions. Steel braces undergo inelastic axial deformations and thus provides an adequate level of structural ductility and hysteretic energy dissipation capability to the frame under cyclic...
loading. Past studies have shown that the slenderness ratio and the width-to-thickness ratio of braces are primarily responsible for achieving enhanced seismic response in SCBFs. An increase in the brace slenderness ratio results in a reduction in its energy dissipation capacity along with a simultaneous increase in the ductility nearing its fracture. Since both energy dissipation capacity and ductility of braces are essential parameters in quantifying the seismic performance of SCBFs, there is a need of establishing the optimum range of brace slenderness ratio and width-to-thickness ratio. The main objective of this study is to find an optimum range as well as the lower limits of these parameters for braces of hollow square steel (HSS) sections. An extensive finite element (FE) parametric study has been conducted on a wide range of values of these parameters using a commercial software package ABAQUS. The FE models accounts for the inelastic hysteretic characteristics and the fracture behavior of braces. The results of simulation models matched very well with the past experimental results with respect to the performance points, namely, global buckling, local buckling, fracture initiation, complete fracture and ductility. Finally, the relationship between the lower limit of slenderness ratio and the width-to-thickness of square braces has been established based on the simulation results.

ABSTRACT: Special concentric braced frames (SCBFs) are commonly used to resist the lateral forces in structures located in high-seismic regions. Steel braces undergo inelastic axial deformations and thus provides an adequate level of structural ductility and hysteretic energy dissipation capability to the frame under cyclic loading. Past studies have shown that the slenderness ratio and the width-to-thickness ratio of braces are primarily responsible for achieving enhanced seismic response in SCBFs. An increase in the brace slenderness ratio results in a reduction in its energy dissipation capacity along with a simultaneous increase in the ductility nearing its fracture. Currently, no guidelines are available for the lower limit of slenderness ratio and since both energy dissipation capacity and ductility of braces are essential parameters in quantifying the enhanced seismic performance of SCBFs, there is a need of establishing the optimum range of brace slenderness ratio and width-to-thickness ratio. Therefore, the main objective of this study was to find an optimum range as well as the lower limits of these parameters. An extensive finite element (FE) parametric study has been conducted on a wide range of parameters of hollow circular braces using a commercial software package ABAQUS. A validated simulation model which had the inelastic characteristics of braces and the fracture behavior incorporated was created. The results of simulation models matched very well with the past experimental results with respect to the four performance points, namely, global buckling, local buckling, fracture initiation, and complete fracture. This model paved way for the parametric study which resulted in a deep understanding of the influence of structural parameters on the behavior of braces.

ABSTRACT: A hybrid brace having a buckling-inhibited axially yielding segment and a non-yielding elastic component over a dominant length in sequence can provide a balanced hysteretic response under cyclic loading condition. Braced frames equipped with such a composite brace can dissipate energy in-elastically without any degradation in the lateral strength and stiffness. The enhanced stiffness of the hybrid brace can assist in reducing the drift demands on buckling-restrained braced frame (BRBF) system under the seismic action. The present study is focused on the energy dissipation characteristics of the short length buckling-restrained braces (BRBs). A reduced scale model of the short length BRB has been tested under a gradually increasing reversed-cyclic loading. In order to simulate the behavior of BRB specimens analytically, finite element modelling of the specimen is carried out using a commercial software package ABAQUS CAE. The modeling of short length BRBs and analysis results are discussed in detail in this paper. The hysteretic response obtained from analysis matched well with the test results.

ABSTRACT: Buckling-restrained braced frames (BRBFs) are considered to be one of the efficient lateral force-resisting systems used in buildings located in the seismically active regions. Nearly symmetric hysteretic response of buckling-restrained braces (BRBs) in tension and compression due to the yielding of steel core plates helps the BRBFs to withstand the seismic excitations without causing any extensive damage to the primary frame members. However, BRBFs may exhibit the excessive post-earthquake residual drift response due to the low axial stiffness of BRBs under the strong ground motions. A reduction in the yielding core segments of BRBs results in the improved elastic and post-elastic axial stiffness of BRBs which may help in controlling the excessive residual drift response. This study is focussed on the analytical evaluation of hysteretic response of BRBs of varying lengths using finite element (FE) software. The results of FE study are further used to evaluate the inter-story and residual drift response of a 3-story braced frame fitted with BRBs of short core lengths (referred as SBRBF). Nonlinear dynamic analysis results of SBRBF are compared with the conventional BRBF and concentrically braced frame (CBF). It is concluded that the optimum reduction in yielding core lengths of BRBs can improve the overall seismic response of BRBFs with a reduction in the residual drift response.
This paper presents a study on the development of high-performance finite elements for geometrically nonlinear analysis of frame structures with curved members. Based on the geometrically exact beam theory, a highly efficient and accurate mixed finite element is developed. A new approach is proposed for constructing the independent internal force field by including major terms satisfying equilibrium conditions in the deformed configuration. An element-level equilibrium iteration procedure is employed for the condensation of element internal degrees of freedom during the nonlinear solution. Numerical results are presented to demonstrate the excellent performance of the element developed, and it is shown that even when each structural member is modelled with just one element, accurate solutions can still be achieved.

ABSTRACT: In the first part of this chapter the basic algorithmic structure and performance characteristics of the p-version of the finite element method are surveyed with reference to elliptic problems in solid mechanics. For this class of problems, the theoretical basis of the p-version is fully established, and a very substantial amount of engineering experience covering linear and nonlinear applications is available. It is shown that p-extensions on properly designed meshes make realization of exponential rates of convergence in practical computations possible and provide for the estimation and control of relative errors in terms of any quantity of interest. In the second part the p-version of the finite element method will be extended to a high-order fictitious domain approach, the finite cell method. Whereas the finite cell method inherits the advantages of the p-version with respect to accuracy and robustness, it relieves analysts from the necessity to generate finite element meshes. Thus, it strongly supports the analysis of problems with highly complicated geometry, for which meshing with finite elements would be very difficult. Given the growing demand for verified numerical solutions, the p-version of the finite element and finite cell methods are expected to play an increasingly important role.

Computational Mechanics, 50(4):445–478, 2012. ABSTRACT: The Finite Cell Method (FCM) is an embedded domain method, which combines the fictitious domain approach with high-order finite elements, adaptive integration, and weak imposition of unfitted Dirichlet boundary conditions. For smooth problems, FCM has been shown to achieve exponential rates of convergence in energy norm, while its structured cell grid guarantees simple mesh generation irrespective of the geometric complexity involved. The present contribution first unhinges the FCM concept from a special high-order basis. Several benchmarks of linear elasticity and a complex proximal femur bone with inhomogeneous material demonstrate that for small deformation analysis, FCM works equally well with basis functions of the p-version of the finite element method or high-order B-splines. Turning to large deformation analysis, it is then illustrated that a straightforward geometrically nonlinear FCM formulation leads to the loss of uniqueness of the deformation map in the fictitious domain. Therefore, a modified FCM formulation is introduced, based on repeated deformation resetting, which assumes for the fictitious domain the deformation-free reference configuration after each Newton iteration. Numerical experiments show that this intervention allows for stable nonlinear FCM analysis, preserving the full range of advantages of linear elastic FCM, in particular exponential rates of convergence. Finally, the weak imposition of unfitted Dirichlet boundary conditions via the penalty method, the robustness of FCM under severe mesh distortion, and the large deformation analysis of a complex voxel-based metal foam are addressed.

We conclude our review by briefly discussing some key aspects for the efficient implementation of the finite cell method. We first provide a concise introduction to the basics of the finite cell method. We then summarize recent findings on the treatment of geometric nonlinearities for large deformation analysis, the weak enforcement of boundary conditions, and local refinement schemes. We also discuss the capabilities and advantages of the finite cell method with several challenging examples, e.g. the image-based analysis of foam-like structures, the patient-specific analysis of a human femur bone, the analysis of volumetric structures based on CAD boundary representations, and the isogeometric treatment of trimmed NURBS surfaces. We conclude our review by briefly discussing some key aspects for the efficient implementation of the finite cell method.

ABSTRACT: A new Mixed Cubic Zigzag Theory (CZT(m)) has been developed via the Reissner Mixed Variational Theorem. The assumed kinematic field postulates an in-plane displacement components piecewise cubic along the thickness and a smeared parabolic through-the-thickness distribution for the transverse displacement. The assumed transverse shear stresses profile derives from integration of the three-dimensional equilibrium equations whereas the normal stress pattern is assumed smeared cubic along the laminate thickness. The entire formulation is here developed and the governing equations derived are used to solve the bending problem of a rectangular simply-supported cross-ply plate subjected to a bi-sinusoidal transverse load. In order to assess the predictive capabilities of the CZT(m) model, results are compared with the exact three-dimensional elasticity solution.

ABSTRACT: This paper presents the design optimization of diaphragms for a micro-shock tube-based drug delivery device. The function of the diaphragm is to impart the required velocity and direction to the loosely held drug particles on the diaphragm through van der Waals interaction. The finite element model-based studies involved diaphragms made up of copper, brass and aluminium. The study of the influence of material and geometric parameters serves as a vital tool in optimizing the magnitude and direction of velocity distribution on the diaphragm surface. Experiments carried out using a micro-shock tube validate the final deformed shape of the diaphragms determined from the finite element simulation. The diaphragm yields a maximum velocity of 335 m/s for which the maximum deviation of the velocity vector is 0.62 deg. Drug particles that travel to the destination target tissue are simulated using the estimated velocity distribution and angular deviation. Further, a theoretical model of penetration helps in the prediction of the drug particle penetration in the skin tissue like a target, which is found to be 0.126 mm. The design and calibration procedure of a micro-shock tube device to alter drug particle penetration considering the skin thickness and property are presented.

ABSTRACT: This paper presents the effect of nonlocal scaling parameter on the coupled i.e., axial, flexural, shear and contraction, wave propagation in single-walled carbon nanotubes (SWCNTs). The axial and transverse motion of SWCNT is modeled based on first order shear deformation theory (FSDT) and thickness contraction. The governing equations are derived based on nonlocal constitutive relations and the wave dispersion analysis is also carried out. The studies shows that the nonlocal scale parameter introduces certain band gap region in all wave modes where no wave propagation occurs. This is manifested in the wavenumber plots as the region where the wavenumber tends to infinite or wave speed tends to zero. The frequency at which this phenomenon occurs is called the escape frequency. Explicit expressions are derived for cut-off and escape frequencies of all waves in SWCNT. It is also shown that the cut-off frequencies of shear and contraction mode are independent of the nonlocal scale parameter. The results provided in this article are new and are useful guidance for the study and design of the next generation of nanodevices that make use of the coupled wave propagation properties of single-walled carbon nanotubes.

ABSTRACT: Foam-filled thin-wall structures have exhibited significant advantages in light weight and high energy absorption and been widely applied in automotive, aerospace, transportation and defence industries. Unlike existing uniform foam materials, this paper introduces functionally graded foam (FGF) fillers to fill thin-walled structures, aiming to improve crashworthiness. In this novel structure, the foam density varies throughout the depth in a certain gradient. Numerical simulations showed that gradient exponential parameter m that controls the variation of foam density has significant effect on system crashworthiness. In this study, the single and multiobjective particle swarm optimization methods are used to seek for optimal gradient, where response surface models are established to formulate specific energy absorption and peak crushing force. The results yielded from the optimizations indicate that the FGF material is superior to its uniform counterparts in overall crashworthiness. The data has considerable implication in design of FGF materials for optimizing structural crashworthiness.

ABSTRACT: This research aimed to investigate the seismic behavior and design of the Coupled Steel Plate Shear Wall (C-SPSW). A prototype six-story C-SPSW building was designed based on the model building code. A 40% scale specimen was constructed as the bottom two-and-half-story substructure of the six-story C-SPSW prototype. The reduced scale sub-structural specimen was cyclically tested using the Multi-Axial Testing System (MATS) at the National Center for Research on Earthquake Engineering (NCREE). In addition to the cyclic lateral forces, the constant vertical loading and cyclic overturning moments were applied on the specimen simultaneously. The test results show that the C-SPSW specimen behaved in a ductile manner and dissipated significant amounts of hysteresis energy during the cyclic loadings. Finally, based on the experimental results, the implications in the capacity design for the bottom boundary column are discussed. A numerical simulation using finite element model was conducted. The analytical results quite match the overall and local experimental responses.

ABSTRACT: A computational model was developed to study the nonlinear steady state static response and free vibration of thin-walled carbon nanotubes/fiber/polymer laminated multiscale composite beams and blades. A set of nonlinear intrinsic equations describing the response of rotating cantilever composite beams undergoing large deformations was established. The main assumptions were small local strains and local rotations, large deflections and global rotations. Halpin–Tsu equations and fiber micromechanics were used to predict the bulk material properties of the multiscale nanocomposite. The carbon nanotubes (CNTs) were assumed to be uniformly distributed and randomly oriented through the epoxy resin matrix. Discretized by the Galerkin approximation, eigenvalues and vectors and nonlinear steady state static response of the nanocomposite. The carbon nanotubes (CNTs) were assumed to

ABSTRACT: This paper investigates the nonlinear analysis of energy harvesting from piezoelectric functionally graded carbon nanotube reinforced composite plates under combined thermal and mechanical loadings. The excitation, which derives from harmonically varying mechanical in-plane loading, results in parametric excitation. The governing equations of the piezoelectric functionally graded carbon nanotube reinforced composite plates are derived based on classical plate theory and von Karman geometric nonlinearity. The material properties of the nanocomposite plate are assumed to be graded in the thickness direction. The single-walled carbon nanotubes (SWCNTs) are assumed to be aligned, straight and have a uniform layout. The linear buckling and vibration behavior of the nanocomposite plates is obtained in the first step. Then, Galerkin’s method is employed to derive the nonlinear governing equations of the problem with cubic nonlinearities associated with mid-plane stretching. Periodic solutions are determined by using the Poincare –Lindstedt perturbation scheme with movable simply supported boundary conditions. The effects of temperature change, the volume fraction and the distribution pattern of the SWCNTs on the parametric resonance, in particular the amplitude of vibration and the average harvested power of the smart functionally graded carbon nanotube reinforced composite plates, are investigated through a detailed parametric study.

ABSTRACT: In this paper, the geometrically nonlinear free and forced oscillations of simply supported single
walled carbon nanotubes (SWCNTs) are analytically investigated on the basis of the Euler–Bernoulli beam
theory. The nonlinear frequencies of SWCNTs with initial lateral displacement are discussed. Equations have
been solved using an exact method for free vibration and multiple times scales (MTS) method for forced
vibration and some analytical relations have been obtained for natural frequency of oscillations. The numerical
results reveal that the nonlinear free and forced vibration of nanotubes is effected significantly by both
surrounding elastic medium and CNT aspect ratio.

ABSTRACT: Cylindrical shells exhibit a dense frequency spectrum, especially near the lowest frequency range. In addition, due to the circumferential symmetry, several equal or nearly equal frequencies may occur, leading to a complex dynamic behavior. So, the aim of the present work is to investigate the dynamic behavior and stability of cylindrical shells under axial forcing with multiple equal or nearly equal natural frequencies. The shell is modelled using nonlinear governing equations of motion and using several tools of nonlinear dynamics, a detailed parametric analysis is conducted to clarify the influence of the internal resonances on the bifurcations, stability boundaries, nonlinear vibration modes and basin of attraction of the structure.

ABSTRACT: This paper presents a further investigation into the energy absorbing behaviour of axially splitting and curling square mild steel and aluminium tubes. Both quasi-static and dynamic tests were conducted. A simple quasi-static kinematic model is developed which describes all the main features of the deformation process. It is assumed in this model that cracks start from the four corners and propagate along the axial direction due to continuous fracture/tearing. The free side plates so formed by cracks roll up into four curls with a constant radius. Formulas for the average crush force, curl radius, and the energy absorption are achieved by analysing the ‘far-field’ and ‘near-tip’ deformation events and the bending moment at the crack tip. This quasi-static model is also extended and used for dynamic cases to explore strain-rate effects in splitting square metal tubes. Solutions are presented and detailed comparisons are made between theoretical predictions and experimental results.

Sun, C., Liu, K., Lu, G.: Dynamic torsional buckling of multiwalled carbon nanotubes embedded in an elastic

ABSTRACT: In this paper the dynamic torsional buckling of multi-walled carbon nanotubes (MWNTs) embedded in an elastic medium is studied by using a continuum mechanics model. By introducing initial imperfections for MWNTs and applying the preferred mode analytical method, a buckling condition is derived for the buckling load and associated buckling mode. In particular, explicit expressions are obtained for embedded double-walled carbon nanotubes (DWNTs). Numerical results show that, for both the DWNTs and embedded DWNTs, the buckling form shifts from the lower buckling mode to the higher buckling mode with increasing the buckling load, but the buckling mode is invariable for a certain domain of the buckling load. It is also indicated that, the surrounding elastic medium generally has effect on the lower buckling mode of DWNTs only when compared with the corresponding one for individual DWNTs.

“Plastic deformation, failure and energy absorption of sandwich structures with metallic cellular cores”,
International Journal of Protective Structures, Vol. 1, No. 4, 2010

ABSTRACT: Cellular metals with stochastic, 2D or 3D periodic microstructures can sustain large plastic
deformation at almost constant stress. Due to such excellent energy absorption capability, cellular metals are
very suited to be used as the core of sandwich structures, which have been applied widely to the areas of
aerospace and aeronautical design, the automotive manufacturing, and shipbuilding, as well as the defense and
nuclear industries. Although there is a great deal of research currently available related to the behaviour of
sandwich structures with metallic cellular core under various loading conditions, they are widely scattered in the
literature. This review paper brings together the latest developments in this important research area. Three types
of cellular metals, namely metal foams, honeycombs and prismatic materials and truss and textile based lattice
materials are considered. The responses of sandwich structure with such cores subjected to different loads, i.e.
quasi-static/low velocity compression and indentation, ballistic impact, high speed compression and blast
loading, are reviewed. The emphasis has been placed on their plastic deformation, failure and energy absorption
behaviours.

ABSTRACT: This paper reviews some topics related to the advances and applications of structural impact dynamics in recent years. Dynamic behavior of structural members including tubes, beams and plates under axial or transverse loading, and cellular materials and sandwich structures under impact or blast loading are summarized here. The research methodology involves experimental studies, theoretical modeling, as well as numerical simulations. However, as we mainly focus on the longer time dynamic responses of structures and cellular materials, studies of stress wave propagation and the material’s strain-rate sensitivity are not included. ABSTRACT: Thin-walled tubular structures are widely used as energy absorbing devices. For conventional tubes subject to axial crushing, they usually exhibit a high initial peak force and large fluctuation in the load-displacement curve. In the present study, internal braces were introduced to square and circular tubes to reduce the initial peak and subsequent fluctuation. Crushing test and FE simulation were performed on the internally-braced and conventional tubes that had the same mass. Good agreement between experimental and numerical results was observed. It is shown that tubes with internal braces have lower initial peak and more uniform crushing process than the conventional ones.

ABSTRACT: The LS-DYNA software was employed to analyze the dynamic responses of a sandwich cylindrical shell system under internal blast loading. The system consisted of metallic face sheets and graded aluminum tubular cores with different wall thicknesses. The response of this system was also compared with that of conventional ungraded ones. The dynamic response of graded cylindrical shells with a series of different core arrangements is reported in this paper. The deformation and blast resistance of the structures were discussed in detail, and the optimum sandwich configuration was obtained. The core layers, which had thickness-tapered arrangement from the inner to the outer layer, were favorable for the energy dissipation and the out face-sheet deflection. Finally, two new response types were defined based on the core compression consequence, which is unique to sandwich structures with graded cores.

Abstract: Rigid origami inspires new design technology in deployable structures with large deployable ratio due to the property of flat foldability. In this paper we present a general kinematic model of rigid origami pattern and obtain a family of deployable prismatic structures. Basically, a 4-crease vertex rigid origami pattern can be presented as a spherical 4R linkage, and the multi-vertex patterns are the assemblies of spherical linkages. Thus, this prismatic origami structure is modelled as a closed loop of spherical 4R linkages, which includes all the possible deployable structures consisting of quadrilateral facets and 4-crease vertices. By solving the compatibility of the kinematic model, a new group of 2n-sided deployable prismatic structures with plane symmetric intersections is derived with multilayer, straight and curvy variations. The general design method for the 2n-sided multilayer deployable prismatic structures is proposed. All the deployable structures constructed with this method have one single degree of freedom, can be deployed and folded without stretching or twisting the facets, and have the compactly flat-folded configuration, which makes it have great potential in engineering applications.

ABSTRACT: In this study buckling analysis of solid rectangular plate made of porous material in undrained condition is investigated. The mechanical properties of plate are assumed to vary through the thickness direction. Distributing of the pores through the plate thickness are assumed to be the nonlinear nonsymmetric, nonlinear symmetric, and monotonous distribution. The effect of pores and pores distribution on critical buckling load of porous plate are studied. Effect of fluid compressibility on critical buckling load is investigated in the undrained condition. Also, effect of temperature on fluid compressibility for symmetric porous material plate, choosing a linear function, is examined. The results obtained for porous plates are verified with the known data in literature. References listed at the end of the paper:

The finite element (FE) models have been verified by previous experimental results in terms of deformation pattern, stress-strain curve, and energy dissipation. The verified FE models have then been used in comprehensive numerical analysis of different aluminum honeycombs. Plateau stress, $\sigma_{pl}$, and dissipated energy ($E_t$ for indentation and $E_C$ for compression) have been calculated at different strain rates ranging from $10^2$ to $10^4$ s$^{-1}$. The effects of strain rate and t/l ratio on the plateau stress, dissipated energy, and tearing energy have been discussed. An empirical formula is proposed to describe the relationship between the tearing energy per unit fracture area, relative density, and strain rate for honeycombs. Moreover, it has been found that a generic formula can be used to describe the relationship between tearing energy per unit fracture area and relative density for both aluminum honeycombs and foams.

ABSTRACT: The present paper reports on the post-yield behaviors of an auxetic structure, honeycomb with representative re-entrant topology. Specimens were made of stainless steel and polymer, respectively. Quasi-static uniaxial tensile tests were conducted in the two principal directions, followed by simulations using the commercial code – ABAQUS 6.11-2. The deformation, tensile stress-strain curves and Poisson’s ratio were of interest. A good agreement was observed between the numerical simulations and the experimental results. Subsequently, the effect of cell wall thickness and initial cell angle was studied by means of finite element analysis. An analytical equation was also given for the yield stress of such materials under tension.

ABSTRACT: Monolithic and sandwich structures have been widely used as energy absorption structures in military and civil engineering. This article reviews theoretical analyses of monolithic beams and plates subjected to static loading, impulsive loading and impact by a mass systematically. Experimental data collected from the literatures are compared with these theoretical results. In addition, the critical impulses for the failure of the monolithic structures are also reviewed. Furthermore, sandwich structures under quasi-static, low-velocity impact, high-velocity impact and blast loading, as well as their failure modes, are also summarized. The research methodology involves experimental investigations, theoretical analyses and numerical simulations.

ABSTRACT: The mechanical behavior of aluminum honeycombs subjected to quasi-static combined compression-shear loading was experimentally investigated. Two different deformation patterns were observed, deforming cell walls non-inclined (Mode I) and inclined (Mode II) respectively. For the first time, normal and shear forces of honeycombs deforming in Mode II were measured directly using a tri-axial load cell. It was found that the shear force behavior was very different for Modes I and II, with a negative shear force being observed for Mode II, which was not previously reported. Three aluminum hexagonal honeycombs with different cell configurations (cell size and wall thickness) were tested at two loading velocities of $5 \times 10^{-4}$ and $5 \times 10^{-3}$ m/s, three loading angles of 15°, 30° and 45°, in the two plane orientations, respectively. The effects of loading velocity, loading angle and loading plane were discussed in detail. An empirical model specifically

ABSTRACT: Aluminium honeycomb is a type of cellular material which has high strength to weight ratio and is a good energy absorber. They are used as structural components in various engineering applications.

Comprehensive study has been conducted on the compressive behavior of aluminium honeycombs. However, the research of aluminium honeycombs subjected to other type of loading, such as indentation, is still limited. In this paper, quasi-static and dynamic indentation tests were conducted to study the deformation and energy absorption of three types of HEXCELL aluminium honeycombs with different cell sizes and cell wall thicknesses. Quasi-static tests were conducted by using a universal MTS machine at velocities of 0.05 mm/s, 0.5 mm/s and 5 mm/s, respectively. Dynamic tests were conducted by using a high speed INSTRON machine at a velocity of 5 m/s. Force-displacement curves were plotted in which the total energy absorbed was calculated. The deformation of aluminium honeycombs in indentation tests includes the compression of honeycomb cells under the indenter and tearing of honeycomb cell walls along the indenter edges. The energy dissipated in compression and tearing were calculated and discussed. The effects of cell size, cell wall thickness and loading velocity or strain rate on the plateau stress and energy absorption were analyzed.

Partial Introduction: The problem on the stability of thin plates with a hole under tension at the macrolevel was considered previously in [1–3]. The plates lose stability because of the formation of zones of compressing stresses near the edges of holes. When calculating the deformation, stability, and failure of nanoscale objects, it is necessary also to take into account the surface effect. With decreasing geometrical sizes, the influence of this effect increases. The local loss of stability of a plate with circular nanohole under uniaxial tension was considered by A.O. Bochkarev and M.A. Grekov [4]. In this case, the surface stresses on the circular hole boundary, which define more exactly the known solution of the Kirsch problem for small hole sizes, were taken into account in the subcritical state. It is noted that taking into account the surface stresses at the hole edge results in a loss of stability of the plate under a smaller load than in the classical formulation. The value of the load decreases by 5–7%.

ABSTRACT: Sandwich cellular structure, associated with more excellent mechanical properties and physical characteristic, such as, panel ductility and high core compressibility, is widely used in aerospace, transportation, military equipment and civil infrastructure. Due to the special compression properties of functional graded cores, the graded sandwich structure presented more excellent impact resistance than the ungraded sandwich. This article presents the results of experimental, numerical investigation into the failure mode and dynamic plastic response of layered graded sandwich plate with layered honeycomb cores to air blast loading. The core arrangements (different core density) effects on the structure’s deformation behavior, energy absorption and impact resistance were mainly discussed. Three typical failure modes can be observed, that was, local deformation, global bending and penetration failure. Under specific loading conditions, the graded sandwich had more excellent impact resistant and energy absorption ratio, especially for the density-decreased core arrangement sandwich.

ABSTRACT: The dynamic response of circular sandwich panels with aluminium honeycomb and corrugated cores under projectile impact was investigated experimentally and numerically. Impulse loaded on the panel was controlled by projectile launching velocity and the deformation process of sandwich panels was recorded by a high-speed camera in the experiments. Typical deformation/failure modes of face-sheets and cores were obtained and analysed. The back face-sheet deflections and strain histories of face-sheets were measured and discussed. A parametric study was conducted by LS-DYNA 3D to analyse the effect of geometrical configuration on energy absorption mechanism and back face-sheet permanent deflection of circular sandwich
panels. The results indicated that the impact resistance of the structure was sensitive to geometrical configuration. Increasing face-sheet thickness and core relative density significantly improved sandwich structure impact resistance. Increasing foil thickness improved the panel impact resistance more efficiently than decreasing wall side length. The results have important reference value to guide engineering application of the sandwich structure subjected to impact loading.

ABSTRACT: Loss of stability under uniaxial tension in an infinite plate with a circular inclusion made of another material is analyzed. The influence exerted by the elastic modulus of the inclusion on the critical load is examined. The minimum eigenvalue corresponding to the first critical load is found by applying the variational principle. The computations are performed in Maple and are compared with results obtained with the finite element method in ANSYS 13.1. The computations show that the instability modes are different when the inclusion is softer than the plate and when the inclusion is stiffer than the plate. As the Young’s modulus of the inclusion approaches that of the plate, the critical load increases substantially. When these moduli coincide, stability loss is not possible.

ABSTRACT: The present article focuses on the nonlinear finite element simulation and control of large amplitude vibrations of smart piezolaminated composite structures. Full geometrically nonlinear finite rotation strain–displacement relations and Reissner–Mindlin first-order shear deformation hypothesis to include the transverse shear effects are considered to derive the variational formulation. A quadratic variation of electric potential is assumed in transverse direction. An assumed natural strain method for the shear strains, an enhanced assumed strain method for the membrane strains and an enhanced assumed gradient method for the electric field is incorporated to improve the behavior of a four-node shell element. Numerical simulations presented in this article show the accurate prediction capabilities of the proposed method, especially for structures undergoing finite deformations and rotations, in comparison to the results obtained by simplified nonlinear models available in references and also with those obtained by using the C3D20RE solid element for piezoelectric layers in the Abaqus code.

ABSTRACT: An improved Fourier series method (IFSM) is applied to study the free and forced vibration characteristics of the moderately thick laminated composite rectangular plates on the elastic Winkler or Pasternak foundations which have elastic uniform supports and multipoints supports. The formulation is based on the first-order shear deformation theory (FSDT) and combined with artificial virtual spring technology and the plate-foundation interaction by establishing the two-parameter foundation model. Under the framework of this paper, the displacement and rotation functions are expressed as a double Fourier cosine series and two...
supplementary functions which have no relations to boundary conditions. The Rayleigh-Ritz technique is applied to solve all the series expansion coefficients. The accuracy of the results obtained by the present method is validated by being compared with the results of literatures and Finite Element Method (FEM). In this paper, some results are obtained by analyzing the varying parameters, such as different boundary conditions, the number of layers and points, the spring stiffness parameters, and foundation parameters, which can provide a benchmark for the future research.

ABSTRACT: This paper presents free vibration analysis of open and closed shells with arbitrary boundary conditions using a spectro-geometric-Ritz method. In this method, regardless of the boundary conditions, each of the displacement components of open and closed shells is represented simultaneously as a standard Fourier cosine series and several auxiliary functions. The auxiliary functions are introduced to accelerate the convergence of the series expansion and eliminate all the relevant discontinuities with the displacement and its derivatives at the boundaries. The boundary conditions are modeled using the spring stiffness technique. All the expansion coefficients are treated equally and independently as the generalized coordinates and determined using Rayleigh-Ritz method. By using this method, a unified vibration analysis model for the open and closed shells with arbitrary boundary conditions can be established without the need of changing either the equations of motion or the expression of the displacement components. The reliability and accuracy of the proposed method are validated with the FEM results and those from the literature.

ABSTRACT: In this work, we propose two prismatic piezoelectric solid–shell elements based on fully three-dimensional kinematics. For this purpose, we perform electromechanical coupling, which consists in adding an electrical degree of freedom to each node of the purely mechanics-based versions of these elements. To increase
efficiency, these geometrically three-dimensional elements are provided with some desirable shell features, such as a special direction, designated as the thickness, along which the integration points are located, while adopting a reduced integration rule in the other directions. To assess the performance of the proposed piezoelectric solid–shell elements, a variety of benchmark tests, both in static and vibration analysis, have been performed on multilayer structures ranging from simple beams to more complex structures involving geometric nonlinearities. Compared to conventional finite elements with the same kinematics, the evaluation results allow highlighting the higher performance of the newly developed solid–shell technology.

ABSTRACT: In this paper, the effect of the temperature change on the vibration frequency of mono-layer graphene sheet embedded in an elastic medium are studied. Using the nonlocal elasticity theory, the governing equations are derived for single-layered graphene sheets. Using Levy and Navier solutions, analytical frequency equations for single-layered graphene sheets are obtained. Using Levy solution, the frequency equation and mode shapes of orthotropic rectangular nanoplate are considered for three cases of boundary conditions. The obtained results are subsequently compared with valid result reported in the literature. The effects of the small scale, temperature change, different boundary conditions, Winkler and Pasternak foundations, material properties and aspect ratios on natural frequencies are investigated. It has been shown that the non-dimensional frequency decreases with increasing temperature change. The present analysis results can be used for the design of the next generation of nanodevices that make use of the thermal vibration properties of the nanoplates.

**ABSTRACT:** A newly developed theory for the analysis of tapered sandwich panels with laminated anisotropic facings is presented. Unlike sandwich panels of uniform depth, the response of tapered sandwich panels is counterintuitive. For example, prior studies have demonstrated that a tapered cantilever sandwich beam having constant dimensions at the clamped edge and subjected to a tip load has an optimum taper angle where the tip deflection is a minimum. The decrease in tip deflection with increasing taper angle, despite the reduction in core thickness, is due to the participation of the facings in resisting transverse shear loads. In the present work, we systematically develop a tapered sandwich theory that is simple to use, yet accurately predicts the stresses and deflection of both symmetric and nonsymmetric tapered sections. A novel feature of the analytical model is that the elastic rigidities of tapered sandwich composites are expressed in terms of the familiar A, B, and D matrices that are widely used to analyze the response of laminated plates and sandwich beams of uniform depth. It is shown that the stiffness matrix for a tapered sandwich member exhibits a total of 12 elastic couplings that are absent in sandwich beams of uniform depth. The analytical model predicts large interlaminar shear and normal stresses near the root of the tapered sandwich beam, which can cause delamination failure between the facings and the core. Numerical results obtained using the tapered sandwich theory and two-dimensional finite element models are in good agreement for several case studies.

ABSTRACT: In this study, critical buckling load analysis for first mode of layered functionally graded shell structures made of silicon nitride (Si3N4)/stainless steel (SUS304) systems is studied. The shell structures are considered as three layers and the layer positions are carried out according to L9 (3^3) orthogonal array. The mechanical properties of the layers are calculated according to a simple rule of mixture of composite materials. The mechanical properties of the layers is assumed to be control factors. Optimum layer levels are obtained using signal to noise (S/N) analysis. Significant layers and their percent contributions on the results are detected using analysis of variance (ANOVA). Maximum buckling load value is carried out based on different arrangements of optimum layer levels.

ABSTRACT: This work researches the stability of cylindrical and conical thin-walled tank shells from the basic level in view of both analysis and previous test results. Detailed discussions on failure modes, numerical simulations and re-investigation of test results have been made. The axisymmetric elastic-plastic buckling phenomena, buckling modes and strengths of meridionally compressed and internally pressurized perfect and imperfect cylindrical and conical shells have been investigated in detail. The effects of imperfection wavelength, location along the meridian, orientation, and amplitude of sinusoidal & local imperfections have been thoroughly studied. The worst possible combined effect of an edge restraint and an imperfection in destabilizing such shells has also been discussed. All results are represented and interpreted in such a way that they can easily be understood and used for design purposes. Simplified expressions are obtained for the prediction of axisymmetric elastic-plastic buckling strength of general thin-walled cylindrical and conical shells under the mentioned loading situations. Design recommendations have been proposed. Comparisons with and critical review of few previous research works have as well been thoroughly carried out.

Detailed investigation of the numerous Gent laboratory test results (obtained about 30 years ago at the Laboratory of Model Testing at Gent University, Belgium) on liquid-filled conical shells, shortly called LFC, that have been made in response to a structural disaster in Belgium along with detailed discussions, explanations, and conclusions have been done. Previous LFC-related research works on nonlinear simulation of liquid-filled conical shells with and without geometric imperfections have as well been discussed and few cases have been re-examined for confirmation and further studying purposes. Relevant explanations and conclusions have been given to the outcomes of those works. Moreover, the Belgium (1972) and Canada (1990) steel water tower failure cases have been carefully examined to check and compare their elastic buckling strengths with the applied loads during failure; and to check for any possible roles played by plasticity effects during the collapse.

Previous research works related to the collapse of the water towers have also been discussed. The notion of a “corresponding cylinder” of a liquid-filled conical shell has been introduced which behaves in exactly the same way as the LFC. Detailed and comprehensive investigation of this “corresponding cylinder” was then made with the simple outcome that the liquid-filled cone behaves like a “wet cylinder”, i.e. with respect to its axisymmetric deformation and buckling behavior.

ABSTRACT: In the present study, a simple four-variable trigonometric shear deformation theory considering the effects of transverse shear deformation and rotary inertia is evaluated for the free vibration analysis of antisymmetric laminated composite and soft core sandwich plates. The theory is displacement-based equivalent single-layer theory in which the in-plane displacements use trigonometric function in terms of thickness coordinate, for calculating out-of-plane shear strains. The number of unknown variables involved in the present theory is only four as against five or more than five in case of other higher order theories. The equations of motion are obtained using the principle of virtual work. A closed-form solution for equations of motion is obtained using the Navier’s solution technique. The effects of side-to-thickness ratio, modular ratio and fibre angle are critically assessed for several problems of laminated composite and sandwich plates. The natural frequencies obtained by using present theory are verified by comparing the results with those of other theories and exact elasticity solution wherever applicable.

ABSTRACT: Laminated composite and sandwich structures are lightweight structures that can be found in many diverse applications especially civil, mechanical and aerospace engineering. The rapid increase in the industrial use of these structures has necessitated the development of new theories that suitable for the bending, buckling and vibration analysis of composite structures. Many review articles are reported in the literature on laminated composite plates and shells in the last few decades. But, in the whole variety of literature very few review articles are available exclusively on laminated composite and sandwich beams. In this article, a critical review of literature on bending, buckling and free vibration analysis of shear deformable isotropic, laminated composite and sandwich beams based on equivalent single layer theories, layerwise theories, zig-zag theories and exact elasticity solution is presented. In addition to this, literature on finite element modeling of laminated and sandwich beams based on classical and refined theories is also reviewed. Finally, displacement fields of various equivalent single layer and layerwise theories are summarized in the present study for the reference of researchers in this area. This article cites 515 references and highlights, the possible scope for the future research on laminated composite and sandwich beams.

Solids, pp 1-8, 2018, DOI: 10.1177/1081286518792959

ABSTRACT: This study is devoted to Jacob Pieter Den Hartog’s views about Stephen Prokopovych Timoshenko. Both were outstanding contributors to the mechanics-based design of structures and machines. Additionally, both were refugees, who were running from hardships in their own countries. Den Hartog ran away from economic hardships that befell the Netherlands after World War I. Timoshenko escaped two Russian revolutions that took place in 1917, in addition to the takeover of Kiev by several armies, including foreign ones, and imminent Soviet rule in Ukraine. Their destinies led them to meet at the Westinghouse Electric Corporation in the USA. This study reviews two prime documents associated with their interaction. The first document is the newly discovered letter sent by Den Hartog to Timoshenko half a century ago, specifically, on the occasion of the latter’s 90th birthday in 1968. The second document is the review of the book As I Remember by SP Timoshenko that Den Hartog published in Science magazine, also in 1968. A complex interrelationship emerges between these two scientists. On the one hand, there is a tremendous appreciation felt by Den Hartog toward Timoshenko; on the other hand, one clearly observes Den Hartog’s disapproval of Timoshenko’s ingratitude to the USA, as expressed in Timoshenko’s autobiography, in numerous passages.

Yanqing Wang and Zhiyuan Zhang (Department of Mechanics, College of Sciences, Northeastern University, Shenyang 110819, China), “Non-local buckling analysis of functionally graded nanoporous metal foam nanoplates”, Coatings, Vol. 8, No. 11, 389, 2018

ABSTRACT: In this study, the buckling of functionally graded (FG) nanoporous metal foam nanoplates is investigated by combining the refined plate theory with the non-local elasticity theory. The refined plate theory takes into account transverse shear strains which vary quadratically through the thickness without considering the shear correction factor. Based on Eringen’s non-local differential constitutive relations, the equations of motion are derived from Hamilton’s principle. The analytical solutions for the buckling of FG nanoporous metal foam nanoplates are obtained via Navier’s method. Moreover, the effects of porosity distributions, porosity coefficient, small scale parameter, axial compression ratio, mode number, aspect ratio and length-to-thickness ratio on the buckling loads are discussed. In order to verify the validity of present analysis, the analytical results have been compared with other previous studies.

ABSTRACT: In this work, a modelling strategy based on damage mechanics is presented for Nomex honeycomb core. Application to sandwich beams. The proposed approach is based on the experimental analysis presented by the authors in [1] and consists of the decoupled modelling of the buckling and collapse of cells for the HRH-78 Nomex honeycomb core with two damage parameters. The proposed approach shows good agreement with the experimental tests. The computational cost is low, proving the efficacy of this technique. This strategy may avoid using full 3D models that mimic the real shape and is a step toward a full compression/shear nonlinear model for honeycomb core.

ABSTRACT: This paper presents a moving Kriging meshfree method based on a naturally stabilized nodal integration (NSNI) for bending, free vibration and buckling analyses of isotropic and sandwich functionally graded (FG) plates within the framework of higher order shear deformation theories. A key feature of present formulation is to develop a NSNI technique for the moving Kriging meshfree method. Using this scheme, the strains are directly evaluated at the same nodes as the direct nodal integration (DNI). Importantly, the computational approach alleviates instability solutions in the DNI and decreases significantly computational cost from using the traditional high-order Gauss quadrature. Being different from the stabilized conforming nodal integration (SCNI) scheme which uses the divergence theorem to evaluate the strains by boundary integrations, the NSNI adopts a naturally implicit gradient expansion. The NSNI is then integrated into the Galerkin weak form for deriving the discrete system equations. Due to satisfying Kronecker delta function property of moving Kriging integration (MKI) shape function, the enforcement of essential boundary conditions in the present method is similar to the finite element method. Through numerical examples, the effects of geometries, stiffness ratios, volume fraction and boundary conditions are studied to prove the efficiency of the present approach.

References listed at the end of the paper:
Andreas Apostolatos, Isogeometric analysis of thin-walled structures on multipatch surfaces in fluid-structure interaction”, PhD Thesis, Technical University of Munich, 2018

ABSTRACT: In this thesis, the Isogeometric Analysis (IGA) of thin-walled structures modelled by trimmed Non-Uniform Rational B-Spline (NURBS) multipatches and its application to partitioned Fluid-Structure Interaction (FSI) is detailed. The structural analysis spans from linear two-dimensional elasticity up to three-dimensional geometrically non-linear membrane and Kirchhoff-Love shell analysis. IGA is a modern numerical method for solving Boundary Value Problems (BVPs) which in contrast to the standard Finite Element Method (FEM) uses the exact geometric description of the problem. In the present work, special emphasis is put on the continuity of the solution between trimmed NURBS multipatch surfaces which are standard in Computer-Aided Design (CAD). In this way, no effort is spent in preparing the analysis model as opposed to meshing in standard FEM and smoother approximations of the unknown fields are enabled. The latter is critical for the approximation of problems with high variational index such as the Kirchhoff-Love shell problem. Additionally, surface coupled multi-physics problems such as FSI especially benefit from the smoothness of the solution provided by isogeometric structural analysis. Accordingly, Penalty, Lagrange Multipliers and Nitsche-type methods are detailed and elaborated for the multipatch coupling and the application of weak Dirichlet boundary conditions on such structural models. FSI simulation is of high importance for the prediction of the mutual interaction between a fluid flow and a flexible structure. Typically, the fluid and the structural problems are solved separately while the coupling conditions are satisfied in an iterative manner along their common interface. In this way, the independent use of suitable methods for the discretization of each physical field is enabled. To exploit the benefits of isogeometric structural analysis on multipatches in FSI, a novel isogeometric mortar-based mapping method for real world CAD geometries is elaborated and detailed. Accordingly, field transformations between low order discretized fluid surfaces and trimmed multipatch NURBS representations of the structural surfaces are enabled in order to satisfy the interface constraints. The thesis is complemented with numerical examples in a sequence of increasing complexity, thus extending isogeometric analysis of thin-walled structures on multipatch surfaces to multiphysics problems of the fluid-structure interaction type.

ABSTRACT: Anisogrid structural elements offer significant advantages over conventional stringer-stiffened analogues due to an exceptional strength and stiffness of unidirectional composite ribs, which are used as the main load-bearing elements. The paper presents a numerical solution for buckling of a sandwich cylindrical shell with composite lattice core loaded with hydrostatic pressure. To model the buckling of the shell, the finite element method is used. A parametric analysis on the effect of the number of helical ribs and the orientation angle on the critical hydrostatic pressure is performed. It is revealed that the local, global or coupled buckling modes can be realized in the buckled shell depending on the geometric parameters of the lattice core structure. The parameters at which the shell provides the maximum mass efficiency are determined.

[13] Li Z M and Qiao P 2015 Buckling and postbuckling of anisotropic laminated cylindrical shells under combined external pressure.

The governing differential equations are derived based on the second Piola-Kirchhoff stress tensor and are reduced to a homogenous linear system of equations using differential quadrature method (DQM). The buckling pressures have been calculated for the shell with isotropic core and orthotropic face sheets with 0-degree orientation with respect to the hoop direction. Moreover, buckling pressure reduction parameter has been defined and computed for different imperfection parameters of face sheets and geometrical properties of sandwich shells. The results obtained in the present work are compared with finite element solutions and results reported in the literature and very good agreements have been observed. It is shown that the imperfections have higher effects on the buckling load of thick shells than thin ones. Likewise, it is found that the present method can capture the various geometrical imperfections observed during the manufacturing process or service life.

ABSTRACT: A new analytical solution is presented for functionally graded (FG) beams to investigate the bending behaviour under the hygro-thermo-mechanical loading using a new fifth order shear and normal deformation theory (FOSNDT). The material properties of the FG beam are varied along the thickness direction according to the power law index. In the present theory, a polynomial shape function is expanded up to fifth-order in terms of thickness coordinate to consider the effects of transverse shear and normal deformations. The present theory is free from the shear correction factor. Using the Navier’s solution technique the closed-form solution is obtained for simply supported FG beams. All the results are presented in non-dimensional form and validated it by developing the classical beam theory (CBT), first order shear deformation theory (FSDT by Mindlin) and third order shear deformation theory (TSDT by Reddy) considering the hygro-thermo-mechanical loading effects which is mostly missing in the literature. It is noticed that the presented FOSNDT is very simple and accurate to predict the bending behaviour of FG beams under linear and non-linear hygro-thermo-mechanical loadings.

ABSTRACT: In the context of its title, this paper we discuss two letters sent to S. P. Timoshenko (1878–1972), as well as a letter of response sent by Timoshenko to Grigolyuk. B. G. Galerkin (1871–1945) is the author of the first letter to S. P. Timoshenko. Second letter to him is by E. I. Grigolyuk. The letters are concerned with the method known as the Galerkin method (in the West), or the Bubnov-Galerkin method or the Bubnov method (in Russia). The letters are fully reproduced here in English translation. Their originals in Russian language are stored at the Timoshenko Archive at Stanford University. The copies of the originals are also obtainable from the authors. Galerkin’s letter appears to be the only document until now where B. G. Galerkin relates to this method, apart from his 1915 paper. The author of the second letter is E. I. Grigolyuk (1923–2005). Grigolyuk suggests to Timoshenko to co-author a paper on the priority associated with the Galerkin method, claiming that it belongs solely to I. G. Bubnov (1872–1919). Although a joint paper by Timoshenko and Grigolyuk was never written, Timoshenko expressed an interest in such an endeavor. These correspondents, namely, B. G. Galerkin, S. P. Timoshenko, and E. I. Grigolyuk have made important contributions to theoretical and applied mechanics of the last century, and their interaction appears to be of interest to the mechanics community. This paper is devoted to their correspondence concerning the priority of authorship, that was questioned by both S. P. Timoshenko and E. I. Grigolyuk, albeit in a different manner.

ABSTRACT: Cylindrical shells and conical shells have been analysed and tested separately for the last decade. However, due to new manufacturing techniques and the use of composite material systems more complex structures can be made. By combining a cylindrical shell and a conical shell one structural component can be created: a cylindrical-conical shell. This is a potential design solution for launch vehicle structures, but there is limited research available about it. Not much is known about the buckling behaviour or imperfection sensitivity of these structures, especially not for sandwich composite shells. Moreover, there are no design guidelines for the buckling of sandwich composite cylindrical-conical shells. SP-8007 and SP-8019 are commonly used guidelines for the design of launch vehicle structures; however, these are only valid for cylindrical shells and conical shells separately. These guidelines also only address composite shells and do not account for sandwich composite shells. The buckling behaviour and imperfection sensitivity has to be fully understood in order to develop new guidelines for sandwich composite cylindrical, conical, and cylindrical-conical shells. Therefore,
the purpose of this research is to better understand the buckling behaviour and imperfection sensitivity of sandwich composite cylindrical, conical, and cylindrical-conical shells. The research focuses on using finite element analysis to study the buckling behavior and imperfection sensitivity of the shells. Models are created of the sandwich composite cylindrical shell, conical shell, and cylindrical-conical shell. Different modelling techniques are compared to find out how to represent a sandwich composite shell. This is done by performing an element study, a mesh convergence study, and a study on the analysis parameters. Moreover, the buckling behavior of the individual shells are compared with the buckling behavior of the combined structure. Different shell geometries such as height of the cone, angle of the cone, and radius of curvature at the transition are used for the comparison. To further investigate the difference between the shells, both linear and non-linear analyses are performed. A comparison is made between the buckling loads, mode shapes, and force-displacement graphs. To investigate the imperfection sensitivity of the different shells, axisymmetric and eigenmode imperfections are added using different amplitudes based on a percentage of the wall thickness.

From the results it could be observed that the buckling behavior of the sandwich composite cylindrical and conical shells without initial imperfections can be captured by both the eigenvalue analysis and the dynamic implicit analysis. However, for the sandwich composite cylindrical-conical shell the eigenvalue analysis is not able to accurately capture the highly non-linear behavior. This can be explained due to the large radial displacement happening at the transition area for the dynamic implicit analysis. The result of this is that the dynamic implicit analysis model is less stiff compared to the eigenvalue analysis model resulting in a lower buckling load. In order to investigate if the non-linear behavior at the interface (location where the conical shell intersects with the cylindrical shell) can be mitigated, a radius of curvature was added to the structure. This was done in order to create a smooth transition at the interface. From the results it could be seen that by adding a radius of curvature the difference between the eigenvalue analysis and dynamic analysis decreased. Moreover, a reinforcement was added to the structure to stiffen the structure at the interface. The results show that this indeed mitigates the non-linear behavior and can give a dynamic implicit buckling load close to the eigenvalue analysis buckling load. From these results it can be concluded that if the non-linear effects are mitigated, the eigenvalue analysis is able to give a buckling load prediction of the sandwich composite cylindrical-conical shell. Moreover, the imperfection sensitivities were compared for the different shells. A similar imperfection sensitivity to geometrical imperfections was observed for the cylindrical shell and conical shell. However, when looking at the imperfection sensitivity of the cylindrical-conical shell it could be seen that the shell is not as sensitive to geometrical imperfections. This can be explained by the fact that the behavior at the transition is dominating the buckling behavior of the whole structure. The results obtained from the thesis show the importance of the non-linear behavior at the transition for the sandwich composite cylindrical-conical shell. This means that for further research it is important that the non-linear effects are included when analysing such a structure.

ABSTRACT: Protein microtubules are one of the most effective intracellular components. The microtubules structure is in a manner that their behaviour is similar to that of the orthotropic materials. Therefore, in this paper, size-dependent vibration of the anisotropic protein microtubule is studied. For this purpose, using a first shear deformable shell model and based on couple stress theory, new equations are developed for the dynamic behavior of anisotropic protein microtubule. After solving the governing equations of microtubule motion, the effects of cytoplasm environment, microtubule dimensions and its mechanical properties, and material length scale parameters on the natural frequency of microtubules are investigated.

ABSTRACT: Since Euler’s elastica, buckling of straight columns under axial compression has been studied for more than 260 years. A low width-to-length ratio column typically buckles at a critical compressive strain on
the order of 1%, after which the compressive load continuously increases with the displacement. Here using a general continuum mechanics-based asymptotic post-buckling analysis in the framework of finite elasticity, we show that a straight hyperelastic column under axial compression exhibits complex buckling behavior. As its width- to-length ratio increases, the column can undergo transitions from continuous buckling, like the Euler buckling, to snapping-through buckling, and eventually to snapping-back buckling. The critical width-to-length ratios for the transitions of buckling modes are determined analytically. The effect of material compressibility on the buckling modes and their transitions is further investigated. Our study provides new insights into column buckling.

ABSTRACT: This paper concentrates on the work by Petrus van Musschenbroek published in 1729, constituting apparently the first study in the literature on column buckling. To understand the significance of Musschenbroek's contribution, we provide the combined personal, historic and scientific contexts in which he carried out his studies; he was the first researcher to deal with the failure of compressed elements as a new phenomenon. Most unfortunately, his name is not currently known except for a small circle of historians of science, whereas engineering students at present are told that buckling should be associated with the name of Leonhard Euler. We fully share the idea of Benvenuto stating that "Musschenbroek's experimental law is of considerable historical interest". The contributions in his 1729 book are shown not only to include his experimental work but Musschenbroek also devised a design procedure for column buckling. The 1729 book by Musschenbroek is entitled: "Physicae experimental et geometricae dissertations". This 1729 book contains a section in Chapter 9 on Strength of Solids under the title, "Introductio ad cohaerentiam corporum firmorum". The studies on resistance of columns under compression are included in this chapter.

ABSTRACT: Initial residual stress is omnipresent in biological tissues and soft matter, and can affect growth-induced pattern selection significantly. Here we demonstrate this effect experimentally by letting soft tubes grow in the presence or absence of initial residual stress and by observing different growth pattern evolutions. These experiments motivate us to model the mechanisms at play when a growing bilayer tubular organ spontaneously displays buckling patterns on its inner surface. We demonstrate that not only differential growth, geometry and elasticity, but also initial residual stress distribution, exert a notable influence on these pattern phenomena. Prescribing an initial residual stress distribution offers an alternative or a more effective way to implement pattern selection for growable bio-tissues or soft matter. The results also show promise for the design of 4D bio-mimic printing protocols or for controlling hydrogel actuators.

ABSTRACT: This present paper concerned with the analytic modelling for vibration of the functionally graded (FG) plates resting on non-variable and variable two parameter elastic foundation, based on two-dimensional elasticity using higher shear deformation theory. Our present theory has four unknown, which mean that have less than other higher order and lower theory, and we denote do not require the factor of correction like the first shear deformation theory. The indeterminate integral are introduced in the fields of displacement, it is allowed to reduce the number from five unknown to only four variables. The elastic foundations are assumed a classical model of Winkler-Pasternak with uniform distribution stiffness of the Winkler coefficient (kw), or it is with variables distribution coefficient (kw). The variable’s stiffness of elastic foundation is supposed linear, parabolic and trigonometry along the length of functionally plate. The properties of the FG plates vary according to the thickness, following a simple distribution of the power law in terms of volume fractions of the constituents of the material. The equations of motions for natural frequency of the functionally graded plates resting on variables elastic foundation are derived using Hamilton principal. The government equations are resolved, with respect boundary condition for simply supported FG plate, employing Navier series solution. The extensive validation with other works found in the literature and our results are present in this work to demonstrate the efficient and accuracy of this analytic model to predict free vibration of FG plates, with and without the effect of variables elastic foundations.

“Structural behaviour of optimised cold-formed steel beams”, Steel Construction – Design and Research, September 2019

ABSTRACT: Cold-formed steel (CFS) members have been significantly employed in light gauge steel buildings due to their inherent advantages. Optimising these CFS members in order to gain enhanced load bearing capacity will result in economical and efficient building solutions. This research presents the
investigation on the optimisation of CFS members subjected to flexural capacity and results. The optimisation procedure was performed using Particle Swarm Optimisation (PSO) method while the section moment capacity was determined based on the effective width method adopted in EN1993-1-3 (EC3). Theoretical and manufacturing constraints were incorporated while optimising the CFS cross-sections. In total, four CFS sections (Lipped Channel Beam (LCB), Optimised LCB, Folded-Flange and Super-Sigma) were considered including novel sections in the optimisation process. The section moment capacities of these sections were also obtained through non-linear Finite Element (FE) analysis and compared with the EC3 based optimised section moment capacities. Results show that compared to the commercially available LCB with the same amount of material, the novel CFS sections possess the highest section moment capacity enhancements up to 65%. In addition, the performance of these CFS sections subject to shear and web crippling actions were also investigated using non-linear FE analysis.

ABSTRACT: Origami, the ancient art of paper folding, has inspired the design and functionality of engineering structures for decades. The underlying principles of origami are very general, it takes two-dimensional components that are easy to manufacture (sheets, plates, etc.) into three-dimensional structures. More recently, researchers have become interested in the use of active materials that convert various forms of energy into mechanical work to produce the desired folding behavior in origami structures. Such structures are termed active origami structures and are capable of folding and/or unfolding without the application of external mechanical loads but rather by the stimulus provided by a non-mechanical field (thermal, chemical,
electromagnetic). This is advantageous for many areas including aerospace systems, underwater robotics, and small scale devices. In this chapter, we introduce the basic concepts and applications of origami structures in general and then focus on the description and classification of active origami structures. We finalize this chapter by reviewing existing design and simulation efforts applicable to origami structures for engineering applications.

This paper investigates the free vibration and compressive buckling characteristics of functionally graded graphene nanoplatelets reinforced composite beams with open edge cracks. Materials, Vol. 12, 1412, 2019

ABSTRACT: This paper investigates the free vibration and compressive buckling characteristics of functionally graded graphene nanoplatelets reinforced composite (FG-GPLRC) beams containing open edge cracks by using the finite element method. The beam is a multilayer structure where the weight fraction of graphene nanoplatelets (GPLs) remains constant in each layer but varies along the thickness direction. The effective Young’s modulus of each GPLRC layer is determined by the modified Halpin-Tsai micromechanics model while its Poisson’s ratio and mass density are predicted according to the rule of mixture. The effects of GPLs distribution pattern, weight fraction, geometry, crack depth ratio (CDR), slenderness ratio as well as boundary conditions on the fundamental frequency and critical buckling load of the FG-GPLRC beam are studied in detail. It was found that distributing more GPLs on the top and bottom surfaces of the cracked FG-GPLRC beam provides the best reinforcing effect for improved vibrational and buckling performance. The fundamental frequency and critical buckling load are also considerably affected by the geometry and dimension of GPL nanofillers.

Medeiro (Department of Structural Engineering, Universidade Federal de Minas Gerais, Belo Horizonte, MG, Brasil), “Evaluation of alternative materials in a wing fixed leading edge to support UAS impact”, Proceedings of the XL Ibero-Latin American Congress on Computational Methods in Engineering (XL CILAMCE), Natal/RN, Brazil, 11-14 November 2019

ABSTRACT: In aeronautics, the risk of an airborne impact between an aircraft and other elements such as birds, hails and other small vehicles must be evaluated. The impact of an Unmanned Aerial Systems (UAS), for example, can be more critical for an aircraft than a bird strike, as reported in a study published by the Federal Aviation Administration (FAA) in 2016. In order to make structures withstand impact with stiffer elements and minimize the increase in their weight, new aircrafts have to be reinforced with alternative materials. In the present paper, a commercial aircraft Wing Fixed Leading Edge (WFLE) reinforced with a triangular structure and other reinforced with sandwich structure made up of aluminum plies and a hexweb aluminum flexcore are subjected to an impact with an UAS. It will be verified if the lithium-ion battery from the small vehicle would penetrate into the airframe when the impact occurs at the airliner cruising speed. The UAS considered is a quadcopter configuration intended for recreational and commercial aerial photography with a 1.2 kg mass. The UAS components were proportionally increased in order to make the small vehicle to be similar to a 1.8kg bird prescribed in requirement FAR 25.571(e). The impact analyzes will be carried out using explicit finite element models of NASTRAN software. The HYPERMESH software will be used for generating finite elements mesh. The Lagrangian approach will be used to model the UAS and the WFLE. For strength analysis of WFLE skin elements will be adopted the Johnson-Cook failure model based on deformations.

ABSTRACT: Nonlinear bifurcations and instabilities of autonomous nonconservative systems, mainly involving the fluid loading of a solid or structure, are reviewed and described in this accessible, pictorial overview. In contrast to the earlier papers in this series (focusing on the instability of elastic deformable systems, and low-order periodically-forced mechanical systems), we focus on a handful of case studies in which the loss of stability is primarily driven by nonconservative forces, i.e. path-dependent forces not associated with a potential. Many systems involving fluid-structure interaction can lose stability under changing conditions in which there is a net flow of energy from the fluid to the structure, sometimes resulting in growing oscillatory behavior. Again, the generic manifestations of instability typically occur within the framework of bifurcation theory. Progression is from simple local bifurcations to more complex global events, and all are related to instructive and intriguing applications. Hopf bifurcations are presented in the context of the galloping and flutter of cables and pipes. Next, Neimark bifurcations appear in aircraft applications involving the free-play fluttering of aerofoils and the wing rock of the Harrier jump-jet. Turning to ships in wind and waves, a homoclinic saddle connection governs the surfing and surf-riding of a vessel in stern seas, while an omega flow explosion can compromise the course-keeping of a passenger ferry in a side wind. Recent work on the dynamic step-buckling of a spherical shell illustrates the role of a center manifold, and the paper ends with a careful study of dissipation-generated instabilities, drawing on the historical struggles to understand the evolution of spinning liquid planets.

Edgars Labans and Chiara Bisagni (Delft University of Technology, Delft, Netherlands), “Buckling of 3D-printed cylindrical shells with corrugated surface”, AIAA SCI-Tech Meeting, January 2020 ABSTRACT: 3D-printing technology opens broad possibilities to manufacture structural shapes which could not be always possible by other methods. In the field of lightweight shells it allows to investigate structures with higher buckling loads than conventional shells. The buckling behavior of 3D-printed shells is studied in this
paper where the shape of the cylindrical shells is modified by adding corrugation in the axial or circumferential directions. The shells are characterized by the amplitude of the corrugation and the number of the sinusoidal waves. Their elastic mechanical behavior is analyzed up to the buckling load. The numerical analysis shows that the modified surface can significantly improve the buckling load and reduces the sensitivity towards geometric imperfections. Prototypes of the shells were manufactured and tested to validate the numerical model. Regardless the experimental scatter, the average buckling load of the optimized corrugated shell twice exceeds the buckling load of the reference circular shell. At the same time stiffness and mass of the shell remain the same.

ABSTRACT: Analytical equation for critical buckling stress of metallic sandwich shell is derived based on well-known Nemeth’s analytical solution for buckling stress of composite monocoque cylindrical shell incorporating the bending rigidity for the sandwich construction. A good agreement for the predicted critical buckling load with finite element analysis result for different geometric parameters is achieved for a rigid core sandwich. Once critical buckling stress of a monocoque shell is obtained based on Nemeth’s solution, then for the sandwich shell the buckling stress can be predicted following a factor of 0.9 (hc/t).

ABSTRACT: The objective of this paper is to assess the in-plane shear buckling of a steel foam sandwich panel that relies on elastic Pasternak foundation. The panel is a combination of solid steel face sheets and foamed steel cores. Foamed steel, that is steel with internal voids, provides enhanced bending rigidity and energy dissipation, and also, the potential to reduce local buckling. The Classic plate theory is employed where their governing equations are solved by the Rayleigh–Ritz method. Uniformly distributed in-plane shear loads are applied to the two opposite edges of the panel and all the four edges of the panel are simply supported. Finally, the effects of the panel parameters, such as the existence of a Pasternak foundation, aspect ratios, and central fraction of the steel foam core, are presented. The results showed that the optimum central fraction of the steel foam core would be 65%, so that the maximum critical shear buckling load has taken place.

ABSTRACT: The present research deals with post-buckling analysis of geometrically perfect/imperfect honeycomb core sandwich panels having graphene platelet (GPL) reinforced face sheets based on general higher order plate model. Honeycomb sandwich panels are often made of aluminum material having low weight but also low stiffness. Here, the application of GPL-reinforced nano-composites as face sheets of sandwich panels has been proposed to enhance their mechanical performance. GPL distributions are considered as uniform and linear models in the face sheets. GPL volume and weight fractions are incorporated to Halpin-Tsai modeling of a nano-composite material. Adopting a general higher order plate theory with five field variables, it is possible to satisfy shear deformation influences needless of adding correction factors. Based on Gibson technique, the hexagonal honeycomb core is equalized with a solid core. Post-buckling load of the sandwich panel has been analytically derived and it is showed that the obtained post-buckling load is dependent on the core thickness, face sheet thickness, cell wall thickness of the core, GPL dispersion in the face sheets and also geometrical imperfection.

ABSTRACT: This paper discusses a global buckling analysis approach for sandwich plates with stiffening ribs. The approach is based on theoretical study and is implemented by the finite element method (FEM). The equilibrium equation corresponding to critical global buckling of the sandwich plate with stiffening ribs under simple supported boundary condition is established by the energy method. The critical buckling solutions for a typical rectangular sandwich plate system (SPS) with a single stiffening rib in the longitudinal direction are then investigated while varying the potential influencing factors. The shear rigidity within the inner core exerts little effect on global buckling and can be neglected. An FEM study on elastic buckling was then conducted via ANSYS software. The advantages of the SPS were highlighted via its elastic eigenvalue buckling numerical analysis with multiple stiffeners. The ultimate buckling loads were computed similarly for different influential factors. Finally, an SPS specimen was tested in a compression test. The results showed that when the rib spacing is large, the local buckling of the plates in the grillage is controllable and the SPS is more resistant to both local and global buckling. The results based on our theoretical method agreed well with those of the FEM and experimental results.

**ABSTRACT:** In this paper, a new analytical approach is developed for buckling of composite sandwich pipes with iso-grid core under uniform external lateral pressure. Firstly, the stiffness contributions of iso-grid cores are evaluated through the new force and moment effect analysis. Then, iso-grid core is transformed into a solid pipe, as the middle layer of the sandwich pipe. The outer, inner, and middle pipes are transformed into an equivalent single-walled pipe. Therefore, composite sandwich pipe with iso-grid core is equalized with a single-walled pipe of the same stiffness. The Rayleigh–Ritz energy method is used to calculate the critical buckling pressure of the composite sandwich pipes with iso-grid cores. The efficiency and accuracy of the presented approach are confirmed by comparing the analytical solutions with finite element results obtained from ABAQUS and other works, showing a good agreement with each other. A parametric study is then carried out.
to investigate the effect of the scale of the structure, outer and inner pipes ply stacking sequence, radius to total thickness ratio, stiffener to outer and inner pipe thicknesses ratio, and stiffener angle on the buckling of sandwich pipes. Finally, applications of the present approach were demonstrated for designing of tendons toward constant various structural applications such as offshore pipelines.

ABSTRACT: Folded plates have attracted profound interest in recent years because of their economic advantages and architectural appearance. In particular, their basic structural response is indeed logical enough, explicit and simple although its required numerical computation procedure is, in a little bit, boring. This type of structures have gained increasing popularity and offers more advantages than more complex structures, such as cylindrical shells, arches and right folded plate frames. Similarly, the thin-walled cellular bridge decks can be treated as a multi-folded plates structure. This study produces an overall review of the historical development of the most popular methods utilized for analysis the folded plate structures which are offered with their applications and how these methods are developed gradually. Four common methods are chosen in this paper to show their highlights of references particularizing in analysis of the above mentioned types of structure; the folded plate elasticity method (FPEM), finite element method (FEM), finite strip method (FSM) and spline finite strip method (SFSM). This investigation covers the elastic behavior, and the experimental researches on the elastic reaction of folded plate structures.

ABSTRACT: The STructural Intensity (STI) describes the energy flow of structure-borne sound within a vibrating structure. For complex structures, the STI is usually obtained from a finite element analysis. At the present time, if structures with arbitrary shapes are considered a measurement procedure for validation purposes is not sufficiently developed. For this reason, a measurement procedure for determining the STI of arbitrarily shaped thin-walled structures is developed within the framework of this research project. This paper deals with the measurement of the STI of a curved shell structure by means of 3D laser vibrometry. Therefore, a measurement procedure is set up that consists of measurement data acquisition, measurement data processing, and a general STI calculation. In this context, the challenges of the measurement procedure should be emphasized, if the structures are not flat but curved. In addition to the flexural vibrations, the extensional
vibrations must also be recorded simultaneously. In the case of curved structures, knowledge of the curvature properties is necessary in addition to the structural vibrations. Finally, the results are compared to the STI obtained from the virtual data of a finite element analysis.

ABSTRACT: Computational modal analysis is usually carried out without consideration of gravity forces. This is well motivated for many structures. However, the vibrational properties of thin-walled plane or shallow shell structures are very sensitive with respect to small modifications of the shell geometry and with respect to in-plane stress and reinforcement. One reason for these in-plane stresses and geometric modifications consists in gravity. This becomes an important issue when using test data obtained under the presence of gravity to update a simulation model where the influence of gravity is neglected. This study investigates the influence of gravity on the modal parameters of a thin rectangular plate and of a thin-walled cubic box. For that, different simulation models are used. While all of them utilize the finite element method, linear and non-linear approaches are
compared. The latter take into account geometrical nonlinearities due to large deformations and the influence of gravity induced stress.

References listed at the end of the paper:

received a major boost due to the popularity of the isogeometric concept [1], along with finite element methods using NURBS or B-Splines as shape functions. Here, one of the decisive features is a relatively easy control of polynomial degree and continuity of shape functions, facilitating discretization of problems for which the weak form has a variational index of 2 or larger, for instance, the classical Kirchhoff-Love thin shell model. Another, most often mentioned feature of isogeometric analysis is the use of “exact” geometry from CAD for computation. Own preliminary studies for buckling and wrinkling analyses of shells and membranes show, that isogeometric shell formulations may provide superior accuracy compared to standard shell finite elements in detecting both critical load levels and physical buckling or wrinkling patterns. That is, isogeometric shell formulations may require only a fractional amount of degrees of freedom for the same level of accuracy obtained with a fine finite element mesh. In this contribution, the reasons for this discrepancy are investigated in a systematic way, i. e., we study the influence of (exact) geometry, polynomial degree, smoothness/continuity and locking effects on the accuracy of results.

ABSTRACT: Global changes of cell shape under mechanical or osmotic external stresses are mostly controlled by the mechanics of the cortical actin cytoskeleton underlying the cell membrane. Some aspects of this process can be recapitulated in vitro on reconstituted actin-and-membrane systems. In this paper, we investigate how the mechanical properties of a branched actin network shell, polymerized at the surface of a liposome, control membrane shape when the volume is reduced. We observe a variety of membrane shapes depending on the actin thickness. Thin shells undergo buckling, characterized by a cup-shape deformation of the membrane that coincides with the one of the actin network. Thick shells produce membrane wrinkles, but do not deform their outer layer. For intermediate micrometer-thick shells, wrinkling of the membrane is observed, and the actin layer is slightly deformed. Confronting our experimental results with a theoretical description, we determine the transition between buckling and wrinkling depending on the thickness of the actin shell and the size of the liposome. We thus unveil the generic mechanism by which biomembranes are able to accommodate their shape against mechanical compression, through thickness adaptation of their cortical cytoskeleton.

Quasay A. Al-Kaseasbeh, “Hysteretic behavior of thin-walled steel tubular columns under constant axial force and cyclic lateral loading”, PhD Dissertation, University of North Dakota, May 2019

ABSTRACT: Thin-walled steel tubular bridge piers (column refers to “bridge pier” in the subsequent text) with either circular and square box cross sections are becoming an increasingly attractive choice as cantilever bridge piers in severe earthquake regions due to their architectural, structural and constructional advantages. However, thin-walled steel tubular columns are vulnerable to local buckling, global buckling or interaction between both under extreme loading events such as strong earthquakes. This buckling results in a significant strength and ductility degradation, which eventually leads to an early and full collapse of the thin-walled steel tubular columns. The work presented in this dissertation investigates the inelastic structural behavior of uniform and newly proposed graded-thickness thin-walled steel tubular circular and square box columns under a constant axial force as a superstructure dead load and uni/bidirectional cyclic lateral loading. First of all, the adopted finite element model (FEM) in ABAQUS/Standard version 6.14, which takes into account the effect of both material and geometric nonlinearities, is verified with the experimental results reported in the literature and
employed for the analysis. Second, the newly proposed graded-thickness column, with size and volume of material equivalent to the BB column, is evaluated under a constant axial force and uni/bidirectional cyclic lateral loading. The proposed graded-thickness column is proved to have significant improvements in the overall hysteretic behavior compared to its counterpart conventional uniform column. Then, the deterioration of the circular bidirectional cyclic loading path over the unidirectional path is emphasized. Finally, a comprehensive parametric study is carried out to investigate the effect of key design parameters including: radius-to-thickness ratio parameter (R_t), width-to-thickness ratio parameter (R_w), column slenderness ratio parameter (λ), magnitude of axial load (P/P_y), and number of loading cycles (N) on the overall hysteretic behavior of uniform and graded-thickness columns under a constant axial force and uni/bidirectional cyclic lateral loading. Subsequently, design formulae have been derived to predict the ultimate strength and ductility of both uniform and proposed graded-thickness columns.

The purpose of present study is to improve the application of GM approach for both beam-columns without intermediate lateral-torsional restraints and with these restraints. The results from the proposed GM are compared with those from Eurocode 3-1-1 interaction equations according to Method 1 and Method 2. A better consistency between the developed GM approach and the Eurocode's interaction equation approach than Eurocode 3 GM approach is observed.

ABSTRACT: The strength of Q460 steel welded thin-walled box columns under biaxial bending is investigated by an FE model. The numerical results, together with available experimental data, are compared with the American Specification ANSI/AISC 360-10. It shows that ANSI/AISC 360-10 provides a good estimate over a wide range of column slenderness ratios; but it severely underestimates the strengths of beam-columns with large slenderness ratios and slightly underestimates those of beam-columns made from HSS with fy=741MPa, and the calculation is more complicated because of using an effective width concept. Therefore, a simple and effective calculation method is proposed. Also, a comparison is made between the proposed formulas and the available experimental results. It shows that the proposed formulas can precisely evaluate the local-overall interactive buckling strength of HSS beam-columns and, in most cases, are also suitable for beam-columns fabricated from mild steels. The proposed formulas are simple and, meanwhile, achieve the same level of accuracy as ANSI/AISC 360-10.

ABSTRACT: The present paper deals with the interactive buckling of thin-walled lipped channel (LC) beams under the bending moment in the web plane when the shear lag phenomenon and distortional deformations are taken into account. A plate model (2D) was adopted for LC beams. The structures were assumed to be simply supported at the ends. A modal method of solution to the interactive buckling problem within Koiter’s asymptotic theory, using the semi-analytical method (SAM) and the transition matrix method, was applied. LC-beams, from short through medium-long via long to very long beams, were considered. The paper focuses on the influence of the secondary global buckling mode on the load carrying capacity for the steel LC-beams under bending.

ABSTRACT: When a higher-order or generalized beam theory is used for the buckling analysis of thin-walled beams, the analysis accuracy critically depends on the number and shapes of the cross-sectional modes associated with warping and distortion. In the study, we propose to use the hierarchically-derived cross-sectional modes consistent with the higher-order beam theory for the analysis of pre-buckling stress and
buckling load. The proposed formulation is applicable to any box beams subjected to arbitrary loads and general boundary conditions. We demonstrate the effectiveness of the proposed method by performing buckling analyses for axial, bending, torsional, and general loadings. Length-to-height ratios of the beams are also varied from 1 to 100. If up to fifty cross-sectional and rigid-body modes are employed, the calculated buckling loads are found to match favorably those predicted by the shell finite element analysis. In that a unified buckling analysis under general loads is developed for box beams, the present study is expected to contribute towards new possibilities for the efficient buckling analysis of more general box beam structures involving several joints.

ABSTRACT: Out-of-plane deformation patterns, such as buckling, wrinkling, scrolling, and folding, formed by multilayer van der Waals materials have recently seen a surge of interest. One crucial parameter governing these deformations is bending rigidity, on which significant controversy still exists despite extensive research for more than a decade. Here, we report direct measurements of bending rigidity of multilayer graphene, molybdenum disulfide (MoS2), and hexagonal boron nitride (hBN) based on pressurized bubbles. By controlling the sample thickness and bubbling deflection, we observe platelike responses of the multilayers and extract both their Young’s modulus and bending rigidity following a nonlinear plate theory. The measured Young’s moduli show good agreement with those reported in the literature (E_{graphene} > E_{hBN} > E_{MoS2}), but the bending rigidity follows an opposite trend, D_{graphene} < D_{hBN} < D_{MoS2} for multilayers with comparable thickness, in contrast to the classical plate theory, which is attributed to the interlayer shear effect in the van der Waals materials.

...
Journal of Intelligent Material Systems and Structures, 2019, DOI: 10.1177/1045389X19828479

ABSTRACT: Based on the electromechanical coupling of piezoelectricity, a piezoelectric ring energy harvester is designed and tested in this study, such that the harvester can be used to power electric devices in the closed-circuit condition. Output energies across the external resistive load are evaluated when the ring energy harvester is subjected to harmonic excitations, and various design parameters are discussed to maximize the power output. In order to validate the theoretical energy harvesting results, laboratory experiments are conducted. Comparing laboratory experiments with theoretical ones, the errors between them are under 10% for the output voltage. Laboratory experiments demonstrate that the ring energy harvester is workable in practical applications.

ABSTRACT: Energy harvesting based on distributed piezoelectric laminated structures has been proposed and extensively investigated for over a decade. The objective of this study is to develop a generic distributed piezoelectric shell energy harvester theory based on a generic linear/nonlinear double-curvature shell, which can be simplified to account for many linear/nonlinear shell and non-shell type distributed energy harvesters. Distributed electromechanical coupling mechanism of the energy harvester was discussed; voltage and power
output across the external resistive load of the shell energy harvester were evaluated. Those equations were explicitly expressed in terms of design parameters and modes. Once the intrinsic Lamé parameters and the curvature radii of the selected host structure are specified, one can simplify the piezoelectric energy harvesting equations to account for common shell and non-shell harvester structures. To demonstrate the simplifications, the generic piezoelectric shell energy harvesting mechanism was applied to a cantilever beam, a circular ring and a conical shell in cases studies. Again, the generic piezoelectric energy harvesting formulations derived from a double-curvature shell can be applied to many shell, e.g., ring shells, cylindrical shell, conical shells, paraboloidal shells, etc., and non-shell, e.g., plates, beams, etc., structures using two Lamé parameters and two curvature radii of the specified structures. Besides, these shell and non-shell structures can be either linear or nonlinear with the von Karman geometric nonlinearity. With given boundary conditions and external loading forces, generated voltage and power across the resistive load in the closed-circuit condition can be estimated for the distributed piezoelectric laminated structure.

ABSTRACT: This chapter involved energy harvesting of a simply supported tubular (circular) cylindrical shell laminated with piezoelectric patches. The distributed modal energy generations using different energy harvester patch sizes (i.e., (1 mm,3.6°) in Case 1, (10 mm,30°) in Case 2, and (20 mm,60°) in Case 3) at various mode numbers were evaluated in case studies. Analytical and simulation results suggest that the maximum magnitude of the spatially distributed modal energies changes at various modes in two cases, due to the patch size enlarged or the number of energy harvester patches in the circumferential direction decreased. It should be noted that the signal averaging effects on energy harvester patches become more significant when the patch size continuously increasing. Additionally, the bending energy components are much smaller than the circumferential membrane energy component, and they increase when mode number increases. Furthermore, the maximum magnitude of the (m, n)th modal energy, in general, increases when energy harvester’s thickness h, or shell’s thickness h increases, but decreases when the shell radius R increases. A tubular shell energy harvesting system was designed and tested in the StrucTronics and Control Laboratory at Zhejiang University. Experimental results suggest that there is an optimal external loading resistance leading to the maximal power output. Both analytical predictions and experimental data were compared favorably. These data evaluated in this study can be used as guidelines to design the optimum piezoelectric energy harvester in practical engineering applications.

ABSTRACT: The non-uniform welding stress distribution in large thin-walled cylindrical structures easily causes the buckling distortion due to weak structural stiffness and nonlinear geometric deformation. The non-uniform temperature field model induced by friction stir welding is analytically developed and is used to theoretically deduce the non-uniform stress model in the weld region. Both the two models are verified by the experimental data. A prediction model of critical buckling load is established for large thin-walled cylindrical structures considering the non-uniform welding stress distribution. The deflection function for buckling analysis is developed by using polynomials and the Chebyshev polynomials of the first kind that satisfy the boundary conditions along the four edges of the structure. The critical buckling loads are calculated for various cylindrical welded shell structures, which obviously decrease with the increase of the diameter-thickness ratio and the length-diameter ratio. The mitigation of buckling distortion is achieved by the correlation of the buckling load and the welding stress with various welding process parameters. The results are beneficial for the determination of geometric configuration and welding process parameters for large thin-walled cylindrical structures in fabrication of propellant tanks of launch vehicles.

The spherical shell is the optimal shape for underwater pressure resistant structures. The results show that Cassini oval pressure hulls with the shape index of 0.10 can resist about 0.30 and one spherical pressure hull with the diameter of 2 m is devoted. Such hulls are numerically studied in the case of constant volume, material properties, and wall thickness. The results show that Cassini oval pressure hulls with the shape index of 0.10-0.11 can resist about 4% more external pressure than the spherical one. This deviates from the classical mechanics conclusion that spherical shell is the optimal shape for underwater pressure resistant structures.
Shell buckling is known for its extreme sensitivity to initial imperfections. It is generally understood that this sensitivity is caused by subcritical (unstable) buckling, whereby initial geometric imperfections rapidly erode the idealized buckling load of the perfect shell. However, it is less appreciated that subcriticality also creates a strong proclivity for spatially localized buckling modes. The spatial multiplicity of localizations implies a large set of possible trajectories to instability—also known as spatial chaos—with each trajectory affine to a particular imperfection. Using a toy model, namely a link system on a softening elastic foundation, we show that spatial chaos leads to a large spread in buckling loads even for seemingly indistinguishable random imperfections of equal amplitude. By imposing a dominant imperfection, the strong sensitivity to random imperfections is ameliorated. The ability to control the equilibrium trajectory to buckling via dominant imperfections or elastic tailoring creates interesting possibilities for designing imperfection-insensitive shells.

Bharat Bhaga and Craig A. Steeves, “Modeling hybrid polymer–nanometal lightweight structures”, Aerospace
ABSTRACT: Increasing the environmental sustainability of aviation is a key design goal for commercial aircraft for the foreseeable future. From the perspective of structural engineering, this is accomplished through reducing the mass of aircraft components and structures. Advanced manufacturing techniques offer new avenues for design, enabling more complex structures which can have highly tailored properties. One advanced manufacturing concept is the use of 3D printed polymer preforms that are coated with nanocrystalline metal through electrodeposition. This enables the use of high-performance materials in virtually any geometry. To exploit this manufacturing approach, it is incumbent to have well-established mechanical models of the behavior of such hybrid structures. In particular, hybrid polymer–nanometal structures tend to fail due to compressive instabilities. This paper describes a model of local shell buckling, a typical compressive instability, as it applies to hybrid polymer–nanometal structures. The analysis depends upon the Southwell stress function model for radially loaded solids of rotation, and couples this with the Timoshenko analysis of local shell buckling. This combination is applicable to a range of practical configurations for truss-like hybrid structures.

SIGNIFICANCE: Kirigami—the Japanese art of cutting paper—has become an emergent tool to realize highly stretchable devices and morphable structures. While kirigami structures are fabricated by simply perforating an array of cuts into a thin sheet, the applied deformation and associated instabilities can be exploited to transform them into complex 3D morphologies. However, to date, such reconfiguration always happen simultaneously through the system. By borrowing ideas from phase-transforming materials, we combine cuts and curvature to realize kirigami structures in which deformation-induced shape reconfiguration initially nucleates near an imperfection and then, under specific conditions, spreads through the system. We envision that such control of the shape transformation could be used to design the next generation of responsive surfaces and smart skins.

ABSTRACT: Kirigami-inspired metamaterials are attracting increasing interest because of their ability to achieve extremely large strains and shape changes via out-of-plane buckling. While in flat kirigami sheets, the ligaments buckle simultaneously as Euler columns, leading to a continuous phase transition; here, we demonstrate that kirigami shells can also support discontinuous phase transitions. Specifically, we show via a combination of experiments, numerical simulations, and theoretical analysis that, in cylindrical kirigami shells, the snapping-induced curvature inversion of the initially bent ligaments results in a pop-up process that first localizes near an imperfection and then, as the deformation is increased, progressively spreads through the structure. Notably, we find that the width of the transition zone as well as the stress at which propagation of the instability is triggered can be controlled by carefully selecting the geometry of the cuts and the curvature of the shell. Our study significantly expands the ability of existing kirigami metamaterials and opens avenues for the design of the next generation of responsive surfaces as demonstrated by the design of a smart skin that significantly enhances the crawling efficiency of a simple linear actuator.

ABSTRACT: Based on the Hermite curve, the buckling behavior of a variable stiffness composite cylindrical shell is investigated. Firstly, the cylindrical shell is unfolded into a plane, and the Hermite curve is taken as the basic reference path on the plane and the variation of the fiber orientation is obtained. Then, the finite element analysis pre-processing program of the variable stiffness composite cylindrical shell is written by Python to develop ABAQUS interactive interface. Finally, the GUI plug-in is developed successfully, the buckling analysis of the constant stiffness and variable stiffness cylindrical shells is carried out and the effect of buckling load on the initial tangential direction q, the initial point tangential magnitude L, the end point tangential direction q, and the end point tangential magnitude L is preliminarily explored. It is found that the buckling load of the variable stiffness cylindrical shell is improved greatly. The secondary development of ABAQUS by Python is used to realize the automatic modeling and calculation analysis of the variable stiffness cylindrical shell parts, which provides research ideas and processes for practical engineering research, and has certain practical significance.

ABSTRACT: Compressive residual stresses generated during thin film deposition may lead to undesirable film damage, such as delamination, buckling, and flaking, ultimately leading to the failure of the device employing the film. Understanding the residual stress generation and role in these damage mechanisms is necessary to preserve thin film integrity and optimize its functional properties. Thin shell theory has been used for decades to predict buckling but the results have not yet been correlated with experimental data since the techniques used to measure stress in metallic films were not able to do so at the required micron scale until recently. Micro scanning X-ray diffraction now enables the direct mapping of the local stress of metallic films. In this paper, finite element method based on thin shell theory and synchrotron X-ray micro diffraction have been used to determine stress maps of thin film buckling patterns. Calculations of the stress distribution in the metallic films have been performed taking into account the buckling geometry determined from optical measurements. Stress distributions over gold blisters and tungsten wrinkles obtained with the two techniques are in fair agreement and
allow for the accurate determination of the stress relaxation profile from the bottom to the top of the buckling, validating the thin shell theory model.

an ideal spherical landscape in both regimes. Upon approaching the buckling bifurcation at response state for nonlinear shallow shell equations about the Pogorelov mirror extended oscillations, which are well described by linear response. We find systematic expansions of the

\[ p/p_c \ll 1 \]

Two regimes: For \( p/p_c \ll 1 \), buckling patterns in SiAlNx films: From straight-sided to telephone-cord and bubble structures. Acta Mater. 2014, 64, 41–53.

ABSTRACT: This paper is devoted to the buckling problem of the composite cylindrical shell subjected to hydrostatic pressure. Both analytical and numerical methods are applied to investigate the buckling behavior. Based on the study of analytical formulas, it is found that the composite cylindrical shells with the same length-to-diameter ratio, diameter-to-thickness ratio, and type of layup have the same buckling pressure. Thus, a scale model experiment method is then proposed, which uses the scale model to replace the full-scale model in pressure test experiment to reduce the manufacturing cost of the test specimen. The feasibility of this method is verified by numerical calculation. The influences of ply orientation angle and length of shell on buckling shape and critical buckling pressure have been investigated numerically and demonstrated by several examples. Based on the study of the influence of shell length on critical buckling pressure, a modified finite element model, which can overcome the conservatism of optimization result due to the stress concentration caused by boundary conditions, is combined with the genetic algorithm to optimize the laminations for mass reduction.

ABSTRACT: We study the axisymmetric response of a complete spherical shell under homogeneous compressive pressure \( p \) to an additional point force. For a pressure \( p \) below the classical critical buckling pressure \( p_c \), indentation by a point force does not lead to spontaneous buckling but an energy barrier has to be overcome. The states at the maximum of the energy barrier represent a subcritical branch of unstable stationary points, which are the transition states to a snap-through buckled state. Starting from nonlinear shallow shell theory, we obtain a closed analytical expression for the energy barrier height, which facilitates its effective numerical evaluation as a function of pressure by continuation techniques. We find a clear crossover between two regimes: For \( p/p_c \ll 1 \) the postbuckling barrier state is a mirror-inverted Pogorelov dimple, and for

\[ (1-p/p_c) \ll 1 \]

the barrier state is a shallow dimple with indentations smaller than shell thickness and exhibits extended oscillations, which are well described by linear response. We find systematic expansions of the nonlinear shallow shell equations about the Pogorelov mirror-inverted dimple for \( p/p_c \ll 1 \) and the linear response state for \( (1-p/p_c) \ll 1 \), which enable us to derive asymptotic analytical results for the energy barrier landscape in both regimes. Upon approaching the buckling bifurcation at \( p_c \) from below, we find a softening of an ideal spherical shell. The stiffness for the linear response to point forces vanishes \( \propto (1-p/p_c)^{1/2} \); the buckling
energy barrier vanishes $\propto (1 - p/p_c)^{3/2}$ and the shell indentation in the barrier state vanishes $\propto (1 - p/p_c)^{1/2}$. This makes shells sensitive to imperfections which can strongly reduce $p_c$ in an avoided buckling bifurcation. We find the same softening scaling in the vicinity of the reduced critical buckling pressure also in the presence of imperfections. We can also show that the effect of axisymmetric imperfections on the buckling instability is identical to the effect of a point force that is preindenting the shell. In the Pogorelov limit, the energy barrier maximum diverges $\propto (p/p_c)^{-3}$ and the corresponding indentation diverges $\propto (p/p_c)^{-2}$. Numerical prefactors for proportionalities both in the softening and the Pogorelov regime are calculated analytically. This also enables us to obtain results for the critical unbuckling pressure and the Maxwell pressure.

ABSTRACT: The use of the Google Scholar produces about 78,000 hits on the term “Timoshenko beam.” The question of priority is of great importance for this celebrated theory. For the first time in the world literature, this study is devoted to the question of priority. It is that Stephen Prokofievich Timoshenko had a co-author, Paul Ehrenfest. It so happened that the scientific work of Timoshenko dealing with the effect of rotary inertia and shear deformation does not carry the name of Ehrenfest as the co-author. In his 2002 book, Grigolyuk concluded that the theory belonged to both Timoshenko and Ehrenfest. This work confirms Grigolyuk’s discovery, in his little known biographic book about Timoshenko, and provides details, including the newly discovered letter of Timoshenko to Ehrenfest, which is published here for the first time over a century after it was sent. This paper establishes that the beam theory that incorporates both the rotary inertia and shear deformation as is known presently, with shear correction factor included, should be referred to as the Timoshenko-Ehrenfest beam theory.

( Isaac Elishakoff wrote the following for an announcement of a lecture on this topic given at the Mechanics and Computation Seminar (ME395) in 2019 at Stanford University: “At the first glance there might be a confusion about the question in the title. One could retort: “Naturally, it was Timoshenko (1878–1972) who developed this theory!” In his 1977 paper, W.T. Koiter claimed that the Timoshenko beam theory is the illustration of the fact that the theory bearing someone’s name is usually by someone else. Koiter did not know how right he was. Hold your breath: Timoshenko WAS one of the developers of this theory! What is not known widely is that he had a collaborator, namely famous Austrian-Dutch physicist Paul Ehrenfest (1880–1933) whose dissertation was in classical mechanics. How did we find this fact? In defiance of the famous cynical definition by Mark Twain, “Classical work is the work that everyone cites but nobody reads,” this author read original papers and autobiographical book by Timoshenko, many times, as well as widely consulted with Archive of S.P. Timoshenko and Archive of P. Ehrenfest that are housed at Stanford and Leiden universities, respectively. In his forthcoming book titled “Timoshenko-Ehrenfest Beam and Uflyand-Mindlin Plate Theories” (World Scientific, Singapore, 2019) author shows that this theory ought to be called Timoshenko-Ehrenfest beam theory. Author conducted an ‘archeological’ dig as it were, to illuminate the fact that, as the ancient saying states “truth sprouts from the earth.” It is also shown that the Timoshenko-Ehrenfest beam theory is unnecessarily overcomplicated. Simplest possible version of the beam theory that takes into account both shear deformation and rotary inertia is suggested. Dr. Elishakoff is preparing another book tentatively titled “S.P. Timoshenko at 140: Going Strong,” and will appreciate any comment on Timoshenko’s life and/or work.”

Isaac Elishakoff (Department of Ocean and Mechanical Engineering, Florida Atlantic University, Boca Raton, FL 33431-0991), “Stepan Prokofievich Timoshenko and America”, ZAMM, January or February 2019 DOI: 10.1002/zamm.201800338
ABSTRACT: In this essay, we describe relationship of S. P. Timoshenko (1878–1972), who is often identified as “the father of American engineering mechanics” with America, where he arrived in 1922 and stayed until 1964. His autobiography appeared in 1963 in Paris in the Russian language; Timoshenko former students and colleagues at Stanford University arranged its translation into English that appeared in 1968 when Timoshenko became 90 years old. The book provides a testimony of the complex relationship that he developed towards America and Americans. Drawing from various documents in addition to his autobiography, this essay discusses in some detail various facets of his relationship. The main goal of this paper is to show that along harsh criticisms towards United States in his autobiographical book, in various documents he expressed positive views about the US.

ACKNOWLEDGEMENTS: Author wants to express sincere gratitude to Professors Norman Abramson of Southwest Research Institute; Holm Altenbach of Otto-von-Guericke-University, Magdeburg; Igor Andrianov of RWTH Aachen; Zdenek P. Bažant of Northwestern University; Nachum P. Fleishman of Lvov University; Raphael T. “Vibration and buckling of shear deformable functionally graded nanoporous metal foam nanoshells”, Nanomaterials, Vol. 9, 271, 2019

ABSTRACT: This article aims to investigate free vibration and buckling of functionally graded (FG) nanoporous metal foam (NPMF) nanoshells. The first-order shear deformation (FSD) shell theory is adopted and the theoretical model is formulated by using Mindlin’s most general strain gradient theory, which can derive several well-known simplified models. The symmetric and unsymmetric nanoporosity distributions are considered for the structural composition. Hamilton’s principle is employed to deduce the governing equations as well as the boundary conditions. Then, via the Navier solution technique, an analytical solution for the free vibration and buckling of FG NPMF nanoshells is presented. Afterwards, a detailed parametric analysis is conducted to highlight the effects of the nanoporosity coefficient, nanoporosity distribution, length scale parameter, and geometrical parameters on the mechanical behaviors of FG NPMF nanoshells.

ABSTRACT: In this research, the vibration and buckling of three-dimensional graphene foam (3D-GrF) microshells are investigated for the first time. In the microshells, three-dimensional graphene foams can distribute uniformly or non-uniformly through the thickness direction. Based on Love’s thin shell theory and the modified couple stress theory (MCST), size-dependent governing equations and corresponding boundary conditions are established through Hamilton’s principle. Then, vibration and axial buckling of 3D-GrF microshells are analyzed by employing the Navier method and Galerkin method. Results show that the graphene foam distribution type, size effect, the foam coefficient, the radius-to-thickness ratio, and the length-to-radius ratio play important roles in the mechanical characteristics of 3D-GrF microshells.

ABSTRACT: The problem of the motion of an incompressible cylindrical shell with an explosive charge is \( \text{nonstationary problem of the motion of a shell under the action of detonation products} \), Journal of Applied Mechanics and Technical Physics, Vol. 13, No. 4.

ABSTRACT: The aeroelastic stability of a long, thin cylindrical shell with the outer surface exposed to an inviscid, helical flow of air is investigated. The cylinder behavior is described by classical shell equations, whereas the aerodynamic forces are described by the linearized potential theory. The approach that is used herein examines the nature of stability of the system when the system is "slightly" perturbed from its initial equilibrium state. In this paper, numerical results are presented only for the special case of swirl flow around a nonrotating shell, i.e., the axial flow velocity is set to zero. These results indicate that traveling wave type of flutter can be caused by coalescence of backward and forward traveling waves. Two approximate theories are presented and the results are compared.

ABSTRACT: The problem of the motion of an incompressible cylindrical shell with an explosive charge is solved numerically for the propagation of a plane detonation wave from the end of the charge. The strength of
the shell is not taken into account. A three-term equation of state [1] is assumed for the detonation products. A comparison is made with the one-dimensional case.

ABSTRACT: It is experimentally demonstrated that a cylindrical shell subjected to a rotating flow may become dynamically unstable. The flutter motion takes the form of a circumferentially traveling wave. The data confirm qualitatively earlier theoretical predictions, although further refinement of the theoretical modeling of the fluid motion is desirable in order to improve the quantitative agreement between theory and experiment.

ABSTRACT: This paper addresses direct time integration techniques for the transient response analysis of coupled fluid-structure problems treated by a class of surface interaction approximations. Efficient solution of the resulting equations of motion can be achieved by a modular computer implementation in which separate fluid and structure analyzers are interfaced through extrapolation of the coupling terms. Such an implementation is herein called a staggered solution strategy. The conventional realization of this strategy is handicapped, however, by severe temporal stepsize limitations. Several stabilized formulations are introduced, which circumvent such limitations and achieve unconditional stability for certain extrapolators.

ABSTRACT: Doubly asymptotic approximations (DAA) are differential equations for simplified analysis of the transient interaction between a flexible structure and a surrounding infinite medium. These surface interaction approximations approach exactness in the limit of low- and high-frequency motions and effect a smooth transition in the intermediate frequency range. A finite-element DAA formulation for an acoustic medium is presented herein, with attention focused on the first and second members of the DAA hierarchy. The free-vibration and forced-response characteristics of the first and second approximations are examined through specialization to a spherical geometry.

ABSTRACT: This report is a reference manual for the third version of the USA-STAGS Code that calculates the nonlinear transient response of a totally or partially submerged structure to a spherical shock wave of arbitrary pressure profile and source location. USA-STAGS is the…

ABSTRACT: Coupled-field dynamic problems in mechanics have been traditionally solved by treating the entire system as one computational entity. More recently, increasing attention has been directed to an alternative approach; partition the governing equations into subsystems, which are treated by subsystem analyzers. The selection of the subsystems may be based on weak-coupling considerations, widely different time response characteristics, isolation of nonlinear effects, or more pragmatic reasons such as the availability of analyzer software. In a staggered solution procedure the solution state of the coupled system is advanced by sequentially executing the subsystem analyzers. Subsystem coupling terms are accounted for by temporal extrapolation techniques. This paper focuses on the formulation and computer implementation of staggered solution procedures for two-field problems governed by semidiscrete second-order coupled differential equations. Such equations find application in the modeling of structure-fluid, structure-soil and structure-structure interaction. Following an introductory description of candidate problems and general solution strategies, direct time integration methods are formulated and applied to the coupled system. Staggered solution procedures are constructed through two alternative approaches which are based upon partitioning at the difference and differential equation level, respectively. Characteristic equations that govern the stability of the resulting implementations are derived, and the selection of stable extrapolators discussed. Finally, possible extensions of staggered solution procedures to coupled-field static and eigenvalue problems are suggested.

ABSTRACT: A numerical solution technique is presented for determining the dynamic response of a thin, elastic, circular, cylindrical shell of constant wall thickness and density, in a potential fluid. The shell may be excited by any radial forcing function with a specified time history and spatial distribution. In addition, a pressure history may be specified over a segment of the fluid outer boundary. Any of the natural shell end conditions may be prescribed. The numerical results are compared to experimental results for a 1/12-scale model of a nuclear-reactor core-support barrel. Natural frequencies and modes are determined for this model in air, water, and oil. The computed frequencies are within 15 percent of experimental results. A sample application compares the numerical technique to an analytical solution for shell beam modes. The comparison resolves an uncertainty concerning the proper effective mass to use in the analytical technique.

T. Belytschko, H.-J. Yen and R. Mullen (Department of Civil Engineering, Northwestern University, Evanston,
ABSTRACT: The time integration of fluid-structure and soil-structure problem is often quite uneconomical when performed with a single integration method and a single time step. Three techniques for enhancing computational efficiency are presented: explicit-implicit partitions, explicit-explicit partitions with different time steps, and implicit-implicit partitions. The latter two require interpolation and extrapolation on the interface. A model problem is presented for examining the stability of these procedures and stabilization techniques are examined.

ABSTRACT: Computational methods for fluid-structure analysis are surveyed. Emphasis is placed on semi-discretization methods, such as finite element and finite difference methods. Appropriate mesh descriptions and time integration procedures for various classes of problems are discussed. The need for mesh partitions, where the fluid and structure are integrated by different methods, is indicated, and three types of mesh partitions are discussed: explicit-implicit (E-I), implicit-implicit (I-I), and explicit with different time steps (Em-E). Some examples are presented to illustrate the applicability of various methods.

ABSTRACT: Most of the failures of large tanks after severe earthquakes are suspected to have resulted from the dynamic buckling caused by overturning moments of seismically induced liquid inertia and surface slosh waves. In this paper, a nonlinear finite element method is presented which can treat the structural behavior of the tanks in conjunction with fluid, including the dynamics and buckling. Both the formulation and computer implementation aspects are presented. The areas upon which attention is focused are: the mixed Lagrangian-Eulerian kinematical description for modeling fluid subdomains in fluid-structure interaction problems, the finite rotation effects in numerical integration of rate constitutive equations arising in large-deformation analysis and the implicit-explicit finite element techniques for transient analysis. All these nonlinear methodologies have been integrated into a finite element computer code [47]. A number of physically important buckling and dynamic analyses of tanks are being investigated. Various other fluid structure phenomena such as the stability of off-shore structures can be analyzed with this computer program. The proposed nonlinear finite-element procedures can serve as a basis for future developments of various other fluid-structure phenomena such as the transient motion of submerged or partially submerged structures.

ABSTRACT: The May 1983 Coalinga Earthquake provided an opportunity to correlate earthquake performance of cylindrical liquid storage tanks with behavior observed in laboratory shaking table experiments. A 38.5 ft diameter steel water tank which developed typical 'elephant's foot' buckling has been found to be a good prototype for a 12 ft diameter aluminum tank. The properties of the prototype and model are correlated. From these relationships, the measured dynamic stress response of the model is extrapolated to obtain the stresses induced in the prototype.

ABSTRACT: The paper describes the theoretical formulation and computational implementation of a method for treating hull cavitation in underwater-shock problems. In addition, the method can be applied to the analysis of submerged structures that contain internal fluid volumes. In the present implementation, the Doubly Asymptotic Approximation (DAA) serves to simulate a radiation boundary that is located away from the fluid-structure surface at a distance sufficient to contain any cavitating region. The enclosed fluid is discretized with volume finite elements that are based upon a displacement-potential formulation. An explicit time-integration algorithm is used to advance the solution in the fluid-volume region, implicit algorithms are used for the structure and DAA boundary, and a staggered solution procedure has been developed to treat the interface conditions. Results for two example problems obtained with the present implementation show close agreement with those obtained by other methods.

D. F. Fischer and F. G. Rammerstorfer, “Stability of liquid storage tanks under earthquake excitation”, (publisher and date not given in the pdf file; the most recent reference is 1983)
SUMMARY: Based on potential flow theory for incompressible, inviscid fluid flow in conjunction with the response spectrum approach, the maximum pressure distribution in the deformable liquid-filled cylindrical tank is calculated. The coupled fluid-structure interaction problem is solved in a semi-analytical manner. By applying this maximum pressure distribution to the shell incrementally the loss of stability (mainly caused by axial compressive membrane forces near the base) is considered by a non-linear finite element analysis. Particularly the influence of shape imperfections on the stability is investigated in the non-linear numerical calculation.

ABSTRACT: The present paper deals with the numerical calculation of the behaviour of vertical wind-loaded cylindrical shells (large liquid storage tanks) with a very flexible bottom plate resting on an elastic foundation. The base of the tank, i.e. the lower boundary of the shell and the bottom plate, may partially uplift due to the shell deformations under the dead load, a hydrostatic pressure and due to wind forces. This behaviour represents non-linear boundary conditions of the tank wall. Hence, the stability of the wind-loaded tank is extremely influenced by the uplift conditions. This non-linear problem (large deformations and variable contact) is solved by the FE method

“A proposal for the earthquake resistant design of tanks – Results from the Austrian Research Project”, Proceedings of Ninth World Conference on Earthquake Engineering, August, 1988, Tokyo-Kyoto, Japan (Vol. VI)
SUMMARY: An engineering approach is presented for calculating the maximum dynamic pressure distributions caused by horizontal and vertical earthquake excitation of tanks. Three different possibilities for superposing the dynamic pressure components due to the horizontal and the vertical earthquake components on the static pressure and the different modes of wall instabilities are discussed. The results show that the dynamic pressure component caused by vertical excitation must not be neglected especially for tall tanks. An essential aim of this project has been the development of simple formulas and diagrams for engineers dealing with the construction of liquid storage tanks made of steel.

ABSTRACT: In this paper, the governing equations which consider dynamic fluid-structure interaction, modal coupling in both axial and circumferential directions, and dynamic buckling are derived. The various pressure components acting on the shell wall due to a seismic event are also analyzed. The matrix equation of motion for liquid-filled shells is obtained through a Galerkin/Finite Element discretization procedure. The modal coupling among the various combinations of axial and circumferential modes are identified with a particular reference to the fluid-structure system under seismic excitation. Finally, the equations for the dynamic stability analysis of liquid-filled shells are presented.

ABSTRACT: In this paper, applications of the theory developed in the companion paper by Liu and Uras [1] are presented. The effects of various types of ground motion on the dynamic stability of the fluid-structure system are analyzed. The stability criteria of liquid-filled shells subjected to horizontal and rocking excitation, shear loading, bending/shear combined loading, and vertically applied load are established. The resulting instability regions and stability charts are given in tables and in _…-epsilon (Porson) plots. Under horizontal and rocking motion, modal coupling in the circumferential direction as well as in the axial direction is observed. The possible buckling modes for a tall tank can be identified as cos2theta, cos3theta and cos4theta under horizontal and rocking motion, and cos5theta and cos6theta, under vertically applied load. For a broad tank two sets of instability modes are found: cos6theta through cos9theta, and cos12theta through cos14theta under horizontal and rocking motion. When subjected to vertically applied load, the failure modes of a broad tank shift to cos10theta through cos12theta, and cos14theta through cos15theta. The effect of shear load on a broad tank appears to be important only if damping is relatively small. Under bending/shear combined loading, the bending forces dominate the stability of the fluid-filled shells.

ABSTRACT: An experimental investigation was conducted to determine the static and dynamic responses of a specific stiffened flat plate design. The air-backed rectangular flat plates of 6061-T6 aluminum with an externally machined longitudinal narrow-flanged T-stiffener and clamped boundary conditions were subjected to static loading by water hydropump pressure and shock loading from an eight-pound TNT charge detonated underwater. The dynamic test plate was instrumented to measure transient strains and free-field pressure. The static test plate was instrumented to measure transient strains, plate deflection, and pressure. Emphasis was placed upon forcing static and dynamic stiffener tripping, obtaining relevant strain and pressure data and studying the associated plate-stiffener behavior.

SUMMARY: This paper deals with a simple fluid-structure interaction problem of floating bridges under step loading with main emphasis on the non-linear dynamic stability of the structure itself after been simulated by a simple discrete mechanical model. The analysis concerns systems which under the same loading applied statically experience a limit point instability. On the basis of a theoretical discussion of the non-linear response of a single degree-of-freedom model simple conditions for an unbounded motion associated with dynamic buckling have been properly established. According to these conditions one can determine the exact dynamic buckling load without solving the strongly non-linear differential equation of motion. Such a load corresponds to that equilibrium point of the unstable (static) post-buckling path for which the total potential energy of the model becomes zero, while at the same time its second variation is negative definite. This load is also a lower bound in case that damping is included in the analysis. The foregoing conditions of static evaluation of the dynamic buckling load do not hold, in general, for limit point systems of two degrees of freedom. The above theoretical predictions have been confirmed by means of numerical integration of the corresponding non-linear equation of motion.

ABSTRACT: A method for the investigation of the dynamic buckling of liquid-filled shells under horizontal excitation has been developed. Strikingly good agreement has been obtained in comparison to available experimental results. This provides guidelines for a better understanding of stability phenomenon of liquid-filled shells. The importance of modal interaction in the axial as well as circumferential directions is also demonstrated. In particular, the coupling between the nth and (n + 1)th circumferential modes is found to be the major cause for the instability of fluid-structure systems under horizontally applied ground motion. For failure conditions in which the buckling modes are not exactly known from the shaking table experiment, the significant bifurcation solutions can be identified from the present analysis.

ABSTRACT: Explosively generated underwater shock waves may interact with a compliant submerged structure or with the free surface to induce cavitation. A finite element analysis of the former case is described. Discretised equations are derived using a displacement potential as the dependent variable. Formulations for a variety of boundary conditions are described. Computational strategy is discussed. A one-dimensional example is presented and results are shown to be in good agreement with those obtained by the method of characteristics. References listed at the end of the paper:

ABSTRACT: This paper describes a modal method of analysis for the rapid evaluation of the linear elastic response of a ring stiffened circular cylindrical shell subjected to underwater explosion loading. The cylindrical wave approximation is used to define the interactive behavior of structure and fluid at the wet boundary. Two mathematical representations of the incident loading are assessed together with other factors which may influence the cylinder response such as stiffener design. The comparative behavior of frames and plating is studied and and assessment is made of the merits of the method through a comparison with the response predictions obtained from more complex discrete element analyses in which the interaction process is treated using a doubly asymptotic approximation.

ABSTRACT: This paper presents an analytical approach to the modelling of the nonlinear inelastic response of a cylindrical shell to underwater shock wave loading. Material nonlinearity is accommodated by the adoption of a linear elastic/plastic stress/strain relationship and geometric nonlinearity by the retention of second order terms in the deflection components which describe the deformation of the cylinder. A cylindrical wave approximation is used to couple the structural and fluid domains.

SUMMARY: The observed equipartition of kinetic energy between the poloidal (convergence/divergence) and toroidal (strike-slip) parts of the Earth's surface velocity field is evidence that large lateral viscosity variations exist in the mantle. The largest such variations probably occur within the lithosphere, in the form of relatively weak boundaries between nearly rigid plates. To understand better the dynamical effects of such viscosity variations, we study an Earth model consisting of a lithospheric shell of outer radius a with laterally variable thickness h(θ, φ) and viscosity ( , ) overlying a mantle whose viscosity η(r) is a function of depth only. Flow in the model is driven by lateral density variations beneath the shell. An asymptotic (long wave) analysis reduces the dynamics of the shell to a pair of boundary conditions, and shows that the effect of the shell is governed by a single dimensionless parameter, the ‘stiffness’ f= ε(γ − 1), where ε=h/a and (a). A
perturbation analysis for the case of small lateral stiffness variations shows that the poloidal flow generated by an internal load interacts with the stiffness variations to generate additional poloidal and toroidal fields of various wavelengths according to definite selection rules. A simple model in which the shell consists of stiff \((f \gg 1)\) ‘plates’ separated by narrow weak \((f \ll 0.5)\) zones shows that (1) large lateral stiffness variations give rise to surface motion with a substantial toroidal component; (2) the observed surface velocity field is extremely sensitive to lateral stiffness variations, and thus provides poor constraints on the mantle viscosity; (3) lateral stiffness variations have a large (~50 per cent) effect on geoid anomalies if the mantle viscosity increases with depth; and (4) geoid anomalies predicted by models that ignore the order-unity relative change of long-wavelength normal stress across the shell are likely to be in error by 30–50 per cent. These results suggest that previous models may have overestimated the viscosity increase in the lower mantle that is required to fit the geoid data.

ABSTRACT: The nonlinear dynamic response of a cylinder subjected to a side-on, far-field underwater explosion was studied using both numerical and experimental techniques. Both ends of the cylinder were closed with thick flat plates. An explosive charge was located 25 feet (7.62 m) from the cylinder on a line perpendicular to the cylinder axis and equidistant from the cylinder ends. Comparison of axial and hoop strains was made between the strain gage measurements and the numerical results at several different locations on the cylinder. Overall, the comparison was in a good agreement. However, it was found that there were asymmetric strain gage data from the experiment. With the postulation of cylinder rotation so that the charge was not located at center of the cylinder length, an additional numerical study was undertaken to investigate the effect of the rotation on the strain distributions. This study showed improvements of the numerical results compared to the experimental data. The numerical study indicated that the dynamic motion of the cylinder has an accordion mode, a breathing mode and a whipping mode.

ABSTRACT: A mathematical formulation and method of solution for the title problem are developed, and numerical results are presented for excitation by a plane step wave. The formulation is based on the familiar equations of motion for a thin spherical shell and the wave equation for the internal and external fluid domains. The Laplace transform is invoked, and the usual separation of variables method produces modal equations for each component of the Fourier-Legendre series solution. The modal equations are then restructured to facilitate transform inversion, yielding delayed differential equations in time for each response mode of the shell-fluid system, which are integrated numerically in time. Complete response solutions then follow by modal superposition, with special techniques being employed to improve modal convergence. Transient response histories are shown for a step-wave-excited steel shell containing water and submerged in water. Also, these results are compared with their counterparts for an empty submerged steel shell.

ABSTRACT: Doubly asymptotic approximations (DAAs) are approximate temporal impedance relations for a medium in contact with a flexible body. In this paper, the method of operator matching previously used for external acoustic domains is used to develop first- and second-order boundary integral DAAs for internal acoustic domains. Corresponding boundary element forms permit the numerical solution of transient structural acoustics problems with complex geometry. The accuracy of the DAAs is assessed in the following companion paper by comparing DAA and exact solutions for a canonical problem with spherical geometry.

Yuan Weifeng and Wu Lianyuan (Department of Engineering Mechanics, Shanghai Jiaotong University), “”On damage effect distance of shells structure subjected to underwater explosion shock”, Journal of Fuzhou University, April 1994

ABSTRACT: The buckling distance of the cylindrical shell subjected to the shock wave against the weight of explosive and the initial static pressure is considered. The estimating method of stiffened cylindrical shell subjected to underwater explosion shock is developed in terms of buckling of shells. Many exprimental results are explained by the present theory

ABSTRACT: Results are provided for an experimental study of the reaction to internal explosive loading of titanium alloy PT-3V welded cylindrical shells filled with air or water. It is established that shell failure develops a strong scale effect in the form of a sharp reduction in explosion resistance with an increase in dimensions. Recommendations are made for weakening the effect of the scale factor and increasing shell explosion resistance. Semi-empirical equations are obtained which are recommended for evaluating explosion deformation parameters for the shell of a cylindrical explosion protection chamber made of titanium alloy.

ABSTRACT: We present various variational formulations adapted to the problem of dynamic stability analysis of liquid propelled launch vehicles. Sloshing vibrations including surface tension effects, hydroelastic
vibrational and structural acoustic vibrations are analyzed, using appropriate symmetric finite element procedures, in order to obtain accurate modal characteristics of the launcher for stability analysis.

ABSTRACT: The nonlinear interaction problem is analyzed by simultaneously solving the mass, momentum, and energy conservation equations together with appropriate material constitutive equations governing the fluid dynamics of the explosion gaseous product and the water and the structural dynamics of the compliant shell. A finite difference technique in a coupled Eulerian–Lagrangian scheme is used. The computer program PISCES 2DELK is employed to carry out the numerical computations. The results demonstrate that to rigorously analyze the response of a submerged structure to a nearby explosion, the interactions among the explosion shock wave, the structure, its surrounding media, and the explosion bubble need to be considered.

ABSTRACT: A new simplified method of analysis is developed to predict the nonlinear dynamic response of submerged stiffened plates subjected to underwater explosions. The dynamic response of the structure is modelled by using rigid-plastic beam and beam-grillage approaches developed previously for air-blast loaded stiffened plates and the fluid-structure interaction is simulated by applying the simple Hains acoustic approximations directly on the wet surface of the structure. Large-deflection and strain-rate effects are considered and the phenomenon of water cavitation is included by using an appropriate pressure criterion. The mathematical formulation of the coupled field system is briefly outlined and some illustrative examples are presented.

ABSTRACT: SPH (Smoothed Particle Hydrodynamics) is a gridless Lagrangian technique which is appealing as a possible alternative to numerical techniques currently used to analyze high deformation impulsive loading events. In the present study, the SPH algorithm has been subjected to detailed testing and analysis to determine the feasibility of using PRONTO/SPH for the analysis of various types of underwater explosion problems involving fluid-structure and shock-structure interactions. Of particular interest are effects of bubble formation and collapse and the permanent deformation of thin walled structures due to these loadings. These are exceptionally difficult problems to model. Past attempts with various types of codes have not been satisfactory. Coupling SPH into the finite element code PRONTO represents a new approach to the problem. Results show that the method is well-suited for transmission of loads from underwater explosions to nearby structures, but the calculation of late time effects due to acceleration of gravity and bubble buoyancy will require additional development, and possibly coupling with implicit or incompressible methods.

ABSTRACT: The effect of the initial geometric imperfections to the damage response of submerged structures is investigated. The type of the submerged structure investigated is the ring-stiffened long circular cylinders submerged in the fluid. The strain hardening mild steel is used in the analysis. The type of the loading is the underwater shock induced by underwater explosions. The modal imperfection concept has been used to simulate the initial geometric imperfections. The numerical analyses were performed to look into the details of damage response of ring-stiffened cylindrical shells. The following models were considered: (i) three-dimensional infinite ring-stiffened cylinder model, and (ii) three-dimensional finite ring-stiffened cylinder model. A finite element hydrocode was used to numerically predict model responses.

References listed at the end of the paper:

ABSTRACT: A theory is presented to predict the influence of non-linearities associated with the wall of the shell and with the fluid flow on the dynamics of elastic, thin, orthotropic and non-uniform open cylindrical shells submerged and subjected simultaneously to an internal and external fluid. The open shells are assumed to be freely simply supported along their curved edges and to have arbitrary straight edge boundary conditions. The method developed is a hybrid of thin shell theory, fluid theory and the finite element method. The solution is divided into four parts. In part one, the displacement functions are obtained from Sander's linear shell theory and the mass and linear stiffness matrices for the empty shell are obtained by the finite element procedure. In part two, the modal coefficients derived from the Sanders–Koiter non-linear theory of thin shells are obtained for these displacement functions. Expressions for the second and third order non-linear stiffness matrices of the empty shell are then determined through the finite element method. In part three, a fluid finite element is developed; the model requires the use of a linear operator for the velocity potential and a linear boundary condition of impermeability. With the non-linear dynamic pressure, we develop in the fourth part three non-linear matrices for the fluid. The non-linear equation of motion is then solved by the fourth-order Runge–Kutta numerical method. The linear and non-linear natural frequency variations are determined as a function of shell amplitudes for different cases.

ABSTRACT: When the structural response of a submerged structure subjected to UNDERwater EXPlosion (UNDEX) loads is calculated, the shock loading from UNDEX must be estimated accurately. In this paper, firstly, characteristics of free field pressure and those of surface pressure on a cylindrical shell structure are discussed through experimental results. Secondly, through the comparison of numerical simulation results with the experimental results, the capability of simulating UNDEX phenomena is shown. And also, it is shown that fluid-structure interaction plays an important role in UNDEX phenomena. Main conclusions can be summarized as follows. (1) Doubly exponential function proposed here can be fitted to measured free field pressure with accuracy better than 5% for impulse and energy flux density of free field pressure. (2) The reflection factor seems to depend on the distance between explosive and a structure. In these experiments, the shadow effects of the test model to shock wave is so remarkable that the reflection factor of the back surface of the test model becomes about 0.3. (3) There are some occasions that sharp peak pressure is generated on the back surface of a cylindrical shell structure, where elastic stress waves through different paths meet. (4) Fluid-structure interaction greatly influences peak value, impulse and energy flux density of shock loading to the test model. Therefore, it is necessary to take it into account when estimating the shock loading by numerical simulation. (5) Using axi-symmetric numerical simulation model, efficient and reasonably accurate estimation of shock loading to a cylindrical shell structure can be performed.

ABSTRACT: Paper presents an analysis of submerged orthotropic cylindrical shells subjected to underwater shock wave. The equations of motion of orthotropic circular cylindrical shells are used in conjunction with the Reflected-Afterflow-Virtual-Source (RAVS) model to model the fluid-structure interaction. The finite difference method is then employed to solve the governing equation for the problem of the infinitive length orthotropic cylindrical shell subjected to planar shock waves. A comparison of the results respectively obtained by present analysis and USA/LSDYNA3D code is made to verify the present solution. By using the present approach, the effects of orientation a, thickness-radius ratio and curvature on the transient responses of the shell are examined.

ABSTRACT: The purpose of this paper is to clarify dynamic buckling behaviours such as buckling mode and buckling pressure for thin cylindrical shells immersed in fluid subjected to seismic excitations. For this purpose, dynamic buckling experiments of thin cylindrical shells placed inside a rigid liquid container are carried out using a shaking table. These shells and the container are intended to represent thermal baffles and a main vessel of a fast breeder reactor, respectively. The fluid pressure caused by horizontal excitation induces buckling deformation which involves flower-shaped deformation, which is a type of external pressure buckling. The buckling pressure is measured with various types of the test cylinders under seismic excitations and this pressure is confirmed to agree with static buckling pressure predicted by static buckling analysis. It is also found that sub-harmonic vibration occurs under a certain sinusoidal excitation inducing a sudden increase in response displacement at a lower pressure level than the buckling pressure under seismic excitations. Based on these experiments, it is pointed out that, in seismic design, to prevent the buckling of thermal baffles, static buckling analyses can be used as long as sub-harmonic vibration does not occur.

ABSTRACT: Benchmarks for submerged structure response to underwater explosions are compiled. Both analytical and empirical benchmarks are presented; each type has advantages and disadvantages for the purposes of model validation, though no methodology for employing these benchmarks in a model validation effort is proposed. Benchmark computations are also referenced as part of this compilation. Extension of this compilation to floating structure response to underwater explosions, and to hydrodynamic/hydraulic ram problems, is proposed.

ABSTRACT: This paper deals with the transient response of a glass-epoxy composite submersible hull subjected to underwater explosive shock. The doubly asymptotic approximation (DAA) method is employed in this study to describe the fluid-structure interactions. The fluid-structure coupled equations, relating structure response to fluid impulsive loadings, are solved using coupled finite-element and boundary-element codes. Transient stress of the composite submersible hull induced by the underwater explosive shock are studied. Effects of the explosive charge weight and the distance from the target on the transient stress are examined. In addition, a comparison between the transient responses to underwater explosive shock for the composite submersible hull and a steel submersible hull is made.

ABSTRACT: A numerical study was conducted for simplified finite element modeling of stiffened structures under a dynamic loading. The study considered submerged structures subject to an underwater explosion. The objective of this study was to develop a finite element modeling technique which is computationally efficient and still accurate in terms of the structural dynamic response. This paper investigated techniques for smearing of stiffeners, representation of a cylindrical shell by a beam with surface of revolution (SOR), and interface of a cylindrical shell with a SOR beam. The advantage and disadvantage: of those techniques in conjunction with an explicit time-integration scheme were also discussed.

“Nonlinear vibrations and multiple resonances of fluid-filled, circular shells, Part 2: Perturbation analysis”,

ABSTRACT: The nonlinear ordinary differential equations describing the dynamics of a fluid filled circular cylindrical shell, obtained in Part 1 of the present study, is studied by using a second order perturbation approach and direct simulations. Strong modal interactions are found when the structure is excited with small resonant loads. Modal interactions arise in the whole range of vibration amplitude, showing that the internal resonance condition makes the system non-linearizable even for extremely small amplitudes of oscillation. Stationary and nonstationary oscillations are observed and the complex nature of modal interactions is accurately analyzed. No chaotic motion is observed in the case of 1:1:1:2 internal resonance studied.

ABSTRACT: The response of a shell conveying fluid to harmonic excitation, in the spectral neighbourhood of one of the lowest natural frequencies, is investigated for different flow velocities. The theoretical model has
already been presented in Part I of the present study. Non-linearities due to moderately large-amplitude shell motion are considered by using Donnell's non-linear shallow-shell theory. Linear potential flow theory is applied to describe the fluid-structure interaction by using the model proposed by Paidoussis and Denise. For different amplitudes and frequencies of the excitation and for different flow velocities, the following are investigated numerically: (1) periodic response of the system; (2) unsteady and stochastic motion; (3) loss of stability by jumps to bifurcated branches. The effect of the flow velocity on the non-linear periodic response of the system has also been investigated. Poincaré maps and bifurcation diagrams are used to study the unsteady and stochastic dynamics of the system. Amplitude modulated motions, multi-periodic solutions, chaotic responses, cascades of bifurcations as the route to chaos and the so-called “blue sky catastrophe” phenomenon have all been observed for different values of the system parameters; the latter two have been predicted here probably for the first time for the dynamics of circular cylindrical shells.

Branislav B. Pujevic, Miodrag M. Sekulovic and Marija M. Nefovska (Civil Engineering, University of Belgrade, Yugoslavia), “Nonlinear analysis of thin-wall cylindrical liquid storage reservoirs under seismic action”, 12WCEE 2000 (12th European Conference on Earthquake Engineering)

SUMMARY: This paper summarizes some of the results of a comprehensive theoretical investigation concerning the seismic response of ground supported liquid storage reservoirs. Dynamic properties of the fluid-shell interaction system with arbitrary boundary conditions were examined first. Evaluation of the results have shown that the variation of natural frequencies to the geometrical properties and filling ratio are highly dependent to the lateral and circumferential mode number. Finally, the accuracy of Code specified procedures for seismic design are examined and compared with the results obtained from the dynamic nonlinear finite element analysis.

ABSTRACT: This paper presents a computational approach to safety assessment of submerged pipelines, exposed to underwater shock. The fluid–structure interaction between the seawater and pipeline are handled using the coupled finite-element and boundary-element codes, based on the Doubly Asymptotic Approximation (DAA). The shock pressure transmitted from the seawater and sea bottom is calculated based on published empirical equations, which are incorporated into the coupled fluid–structure codes. Four cases of pipeline configurations were modeled and simulated, in this study. The first case is a submerged empty pipeline without any cover, the second case is a submerged empty pipeline with concrete cover, the third case is an empty pipeline buried in sand and the fourth case deals with a fluid-filled pipeline buried in sand. A comparison
between the four pipeline configurations is made, and the effects of the concrete cover and sand for the protection of the pipeline are examined.

ABSTRACT: The general features of an isolated underwater explosion have been extensively studied and are considered to be reasonably well understood. However, our understanding of the interaction which ensues when an explosion occurs in the immediate vicinity of a floating or submerged structure is considerably less well developed. We describe the application of small-scale experiments incorporating cylindrical steel targets instrumented with accelerometers and underwater pressure transducers to investigate this question. Acceleration records clearly show the response of the targets to loading from the separate shock wave and bubble collapse events. Interpretation of this data demonstrates the dominance of bubble collapse loading for underwater explosions in close proximity to a submerged structure.

ABSTRACT: Experimental and numerical investigations were carried out on clamped rectangular plates subjected to underwater explosion loading. Experiments were conducted on rectangular plates of size 0.55Y0.45Y0.004 m using a box model set-up under air-backed conditions in a water tank detonating small charge weights of PEK-I explosive. Corresponding plastic deformation of the plates were measured for different charge weights and stand off distances. Numerical analysis was carried out using the MARC finite element code for various test conditions and the results are compared with experimental results.

“Experimental and numerical investigation on deformation of cylindrical shell panels to underwater explosion”, Shock and Vibration, Vol. 8, pp 253-270, 2001

ABSTRACT: Experimental and numerical investigations on cylindrical shell panels subjected to underwater explosion loading are presented. Experiments were conducted on panels of size 0.8 × 0.6 × 0.00314 m and shell
Simulation response of a submerged spherical shell subjected to strong, plane, incident shock waves, in which elastoplastic material behavior is considered.

ABSTRACT: Based on a procedure which couples the finite element method with the doubly asymptotic approximation, this work addresses the problem of the transient responses of a submerged spherical shell subjected to strong, plane, incident shock waves, in which elastoplastic material behavior is considered. Simulation results indicate that the procedure adopted shows good agreement with related literature, which rise-to-span ratios $h/l = 0.0, 0.05, 0.1$, using a box model set-up under air backed conditions in a shock tank. Small charges of PEK I explosive were employed. The plastic deformation of the panels was measured for three loading conditions. Finite element analysis was carried out using the CSA/GENSA [DYNA3D] software to predict the plastic deformation for various loading conditions. The analysis included material and geometric non-linearities, with strain rate effects incorporated based on the Cowper-Symonds relation. The numerical results for plastic deformation are compared with those from experiments.

SUMMARY: Viscoplastic response of a fully-clamped circular plate to an underwater explosion shock is studied in this paper. Strain-rate effect is included in the response. A fluid-structure interaction model is introduced, which is characterized by two stages: In the early stage, only the shock wave in water is considered, and the motion of structure is neglected. In the second stage, the wave propagation in structure and fluid is disregarded, and only long-term fluid force (added mass) and long-term structural force (membrane stress) are considered. Based on this model, the equation of motion of a fully-clamped circular plate is established, the solutions of which are compared with two experiments. The calculated maximum plastic deformations from present model are close to the observed values. The dependence of maximum plastic deformation on charge weight, plate radius and material property is also discussed.

ABSTRACT: Finite element analysis can be used to predict the transient response of submerged structures that
are externally loaded by an acoustic pressure shock wave resulting from an Underwater Explosion (UNDEX). This class of problem is characterized by a strong coupling between the structural motions and acoustic pressures at the fluid-structure wetted interface. The structural behavior is a combination of long time (low frequency) response dominated by an added mass effect, short time (high frequency) response dominated by radiation damping, and intermediate time-frequency response where both added mass and radiation damping behavior are present. For the finite element method to be useful, the analyst must develop modeling techniques and procedures that yield accurate and computationally tractable solutions. Modeling procedures and guidelines were developed for use with an explicit dynamics code that offers advanced features such as: pressure formulated acoustic elements, surface based fluid-structure coupling, surface based absorbing (radiation) boundaries, and automated incident wave loading for the fluid-structure wetted interface. The modeling guidelines address issues such as: location of the fluid acoustic domain outer boundary, meshing of the acoustic domain, representation of the shock wave, and solution efficiency. These modeling procedures and guidelines are demonstrated with an ABAQUS/Explicit analysis of an UNDEX experiment in which a submerged test cylinder was exposed to a 60-pound HBX-1 explosive charge (Kwon & Fox, 1993).

ABSTRACT: The assessment of the response of naval vessels to underwater shock creates a need for tools that can analyze and design such systems to withstand underwater explosions (UNDEX). This paper describes a preliminary attempt to develop a methodology for the assessment of structural systems to UNDEX effects. A methodology is proposed by which the response of a simplified structural component to UNDEX can be validated through the use of precision impact testing and numerical simulations. An iterative process was used where an UNDEX response, determined through previous results, preliminary UNDEX simulations, and impact simulations, provided the parameters necessary for a precision impact test that generates an equivalent response. Precision impact tests were performed, and the results correlated with the impact simulated data. The results from an UNDEX test were compared with the predictions from the validated numerical code. The structural component in both the tests and simulations was simplified to a flat rectangular panel. The numerical simulations were solved explicitly, and included either the impact loading environment—a hybrid impactor with an initial velocity—or the UNDEX loading environment—a plane shock wave applied to the surface of the target structure. Since close-in and early time UNDEX-related phenomena, such as gas bubble effects, are localized and very complicated, they were ignored in this preliminary phase of the study. Although the proposed methodology could require multiple iterations, the limited scope of this study only included one set of precision-impact tests on each type of material, one UNDEX test against an aluminum panel, and two UNDEX tests against composite panels. Once the methodology using precision shock testing and numerical simulations to validate the UNDEX response had been developed, it was used to develop a “design-for-shock” procedure.

“Simulating cyclic artery compression using a 3D unsteady model with fluid-structure interactions”, Computers
& Structures, Vol. 80, pp 1651-1665, 2002

ABSTRACT: High pulsating blood pressure and severe stenosis make fluid–structure interaction (FSI) an important role in simulating blood flow in stenotic arteries. A three-dimensional nonlinear model with FSI and a numerical method using GFD are introduced to study unsteady viscous flow in stenotic tubes with cyclic wall collapse simulating blood flow in stenotic carotid arteries. The Navier–Stokes equations are used as the governing equations for the fluid. A thin-shell model is used for the tube wall. Interaction between fluid and tube wall is treated by an incremental boundary iteration method. Elastic properties of the tube wall are determined experimentally using a polyvinyl alcohol hydrogel artery stenosis model. Cyclic tube compression and collapse, negative pressure and high shear stress at the throat of the stenosis, flow recirculation and low shear stress just distal to the stenoses were observed under physiological conditions. These critical flow and mechanical conditions may be related to platelet aggregation, thrombus formation, excessive artery fatigue and possible plaque cap rupture. Computational and experimental results are compared and reasonable agreement is found.

Almost all vessels carrying fluids within the body are flexible, and interactions between an excited oscillation of a single-phase fluid flow at low Reynolds number. We review recent advances in understanding the mechanics of composite material vessels and components, PVP 146, PD 18. ASME; 1988. p. 55–62.

ABSTRACT: The practicability of an improved procedure for simulating the response of a surface ship to an underwater explosion is demonstrated by examining transient responses for a 31,000-degree-of-freedom finite-element model of ship-like structure. The fluid model employs spectral elements of various order, and models the cavitating fluid as a nonlinear acoustic medium with a bilinear bulk modulus. The number of fluid degrees of freedom ranges from 10^7 to 10^10. Also studied is the viability of dramatic mesh truncation, which is essential to the feasibility of the procedure. The results indicate that useful simulations may be performed on a modern PC when all of the resource-conserving improvements are fully exploited.

ABSTRACT: Almost all vessels carrying fluids within the body are flexible, and interactions between an internal fluid and wall deformation often underlie a vessel’s biological function or dysfunction. Such interactions can involve a rich range of fluid-mechanical phenomena, including nonlinear pressure-drop/flow-rate relations, self-excited oscillations of single-phase flow at high Reynolds number and capillary-elastic instabilities of two-phase flow at low Reynolds number. We review recent advances in understanding the fundamental mechanics of flexible-tube flows, and discuss physiological applications spanning the cardiovascular system (involving wave propagation and flow-induced instabilities of blood vessels), the respiratory system (involving phonation, the closure and reopening of liquid-lined airways, and Marangoni
flows on flexible surfaces), and elsewhere in the body (involving active peristaltic transport driven by fluid-
structure/muscle interactions).

ABSTRACT: Stainless steel square-honeycombs have been manufactured by slotting together steel sheets and then brazing the assembly. Their out-of-plane compressive response has been measured as a function of the relative density, the ratio of specimen height to cell size, and the degree of constraint associated with bonding of the honeycomb to face-sheets. It has been found that, for the practical range of relative densities (less than 20%), the peak strength is relatively insensitive to both the ratio of the specimen height to cell size and to the presence or absence of bonding to face-sheets. An analytical model, derived from existing models for the buckling of shells, for elastic and plastic buckling of the square-honeycombs is shown to be in good agreement with the experimental measurements.

ABSTRACT: The paper studies the interaction of a spherical shock wave with an elastic circular cylindrical shell immersed in an infinite acoustic medium. The shell is assumed infinitely long. The wave source is quite close to the shell, causing deformation of just a small portion of the shell, which makes it possible to represent the solution by a double Fourier series. The method allows the exact determination of the hydrodynamic forces acting on the shell and analysis of its stress state. Some characteristic features of the stress state are described for different distances to the wave source. Formulas are proposed for establishing the safety conditions of the shell.

ABSTRACT: Surface ship shock trials have been conducted in many countries for shock qualification of ship integrity, systems and subsystems. The ship shock trial identifies design and construction deficiencies that have a negative impact on ship and crew survivability. It also validates shock hardening criteria and performance. However, ship shock trials are costly. As a possible alternative, numerical modeling and simulation may provide viable information to look into the details of dynamic characteristics of ship including component and sub-component level. Ship shock analyses were conducted using finite element based coupled ship and fluid model. Three-dimensional ship shock modeling and simulation has been performed and the predicted results were compared with ship shock test data. Surface ship shock analysis approach is presented and the important parameters are discussed.

ABSTRACT: During World War II many surface combatants were damaged or severely crippled by close-proximity underwater explosions from ordnance that had actually missed their target. Since this time all new classes of combatants have been required to conduct shock trial tests on the lead ship of the class in order to test the survivability of mission essential equipment in a severe shock environment. While these tests are extremely important in determining the vulnerabilities of a surface ship, they require an extensive amount of preparation, man-hours, and money. Furthermore, these tests present an obvious danger to the crew on board, the ship itself, and any marine life in the vicinity. Creating a virtual shock environment by use of a computer to model the ship structure and the surrounding fluid presents a valuable design tool and an attractive alternative to these tests. The research work shown in this paper investigated the accuracy of shock simulation using the shock trials conducted on USS WINSTON S. CHURCHILL (DDG 81) in 2001. All three explosions DDG 81 was subjected...
to are simulated and the resulting predictions compared with actual shock trial data. The ship shock modeling and simulation strategy is discussed and the effects of fluid volume size, mesh density, mesh quality are also investigated.

ABSTRACT: This work compares experimental and numerical results concerning the elastic dynamic response of an air-backed rectangular aluminum plate subjected to an underwater explosion. Experiments were executed in a 4 x 4 x 4 m water tank. A small quantity of charge was applied to ensure the dynamic response of the target plate remained within the elastic range. A highly sensitive combined charge, which consists of a DP60 detonator and a Detasheet, was selected to enable a small quantity of charge to react fully when it explodes in the small water tank. The shock parameters of the combined charge were determined experimentally. Subsequent experiments on a plate panel were affected by an explosion of the aforementioned combined charge at various standoff distances. The plate panel under the same experimental conditions was numerically analyzed using the package USA/DYNA. The acceleration, velocity and strain histories of the target plate obtained from both experimental tests and numerical analysis were compared. The experimental and numerical results correlate well with each other.

ABSTRACT: Three-dimensional collapse of and steady flow through finite-length elastic tubes are studied numerically. The Navier-Stokes equations coupled with large, nonlinear deformation of the elastic wall are solved by using the finite-element software, FIDAP. Three-dimensional solid elements are used for the elastic wall, allowing us to specify any wall thickness required. Plane-strain results for the cross-sectional shape of thinner-walled tubes are validated by comparison with published numerical data. Three-dimensional results for flow through finite-thickness tubes are in excellent agreement with published numerical results based on thin-shell elements, and are used to show the effects of varying wall thickness. Finally, the computational predictions are compared with experimental pressure–area relationships for thick walled tubes. The simulations confirm a previously neglected experimental finding, that the Young wavespeed can be lower between buckling and osculation for thick tubes than for thinner ones.

ABSTRACT: This paper presents experimental results on the nonlinear dynamics and stability characteristics of thin-walled clamped–clamped circular cylindrical shells in contact with flowing fluid. The experiments were conducted with three experimental set-ups: one for experiments with elastomer shells in annular air-flow, the second for elastomer shells with internal air-flow, and the last one for aluminium or plastic cylindrical shells with internal water-flow. In all cases the interaction between the shell and the fully developed flow gives rise to instabilities in the form of static or dynamic divergence at sufficiently high flow velocities. The aim of the experimental study was (i) to gather data on the critical flow velocity for instability and on the post-critical flow/displacement–amplitude relationship, and (ii) to undertake an analysis of the experimental results and to compare them qualitatively with theoretical predictions. The experimental results show a softening type nonlinear behaviour, with a large hysteresis in the velocity for the onset and cessation of divergence.

ABSTRACT: In this study, the nonlinear vibrations are investigated of circular cylindrical shells, empty or fluid-filled, clamped at both ends and subjected to a radial harmonic force excitation. Two different theoretical models are developed. In the first model, the standard form of the Donnell’s nonlinear shallow-shell equations is used; in the second, the equations of motion are derived by a variational approach which permits the inclusion of constraining springs at the shell extremities and taking in-plane inertial terms into account. In both cases, the solution includes both driven and companion modes, thus allowing for a travelling wave in the circumferential direction; they also include axisymmetric modes to capture the nonlinear inward shell contraction and the correct type (softening) nonlinear behaviour observed in experiments. In the first model, the clamped beam eigenfunctions are used to describe the axial variations of the shell deformation, automatically satisfying the boundary conditions, leading to a 7 degree-of-freedom (dof) expansion for the solution. In the second model, rotational springs are used at the ends of the shell, which when large enough reproduce a clamped end; the solution involves a sine series for axial variations of the shell deformation, leading to a 54 dof expansion for the solution. In both cases the modal expansions satisfy the boundary conditions and the circumferential continuity condition exactly. The Galerkin method is used to discretize the equations of motion, and AUTO to integrate the discretized equations numerically. When the shells are fluid-filled, the fluid is assumed to be incompressible and inviscid, and the fluid–structure interaction is described by linear potential flow theory. The results from the
two theoretical models are compared with existing experimental data, and in all cases good qualitative and quantitative agreement is observed.

ABSTRACT: Stainless steel square honeycomb core sandwich and solid monolithic beams have been subjected to high-pressure, short-duration impulses using a shock simulation technique involving high-speed impact of Al foam projectiles. The experiments have been designed to achieve two objectives: (i) to demonstrate the benefits of sandwich construction, and (ii) to assess the fidelity of dynamic finite element calculations in simulating the structural response. The results affirm that, when subjected to impulse levels representative of those associated with nearby explosions, the sandwich beams exhibit smaller displacements than the solid beams at equivalent weight. The benefit is especially large at lower impulses where the effective dynamic strength of the honeycomb core prevents crushing. The measurements and finite element simulations having greatest relevance to the shock resistance are found to correspond closely, particularly the displacements and the core crushing strains. One implication is that the dynamic finite element model has the requisite fidelity at impulse levels of interest.

ABSTRACT: The application of the finite element corotational theory to model geometric nonlinear structures within a fluid–structure interaction procedure is proposed. A dynamic corotational approximately-energy-conserving algorithm is used to solve the nonlinear structural response and it is shown that this algorithm's application with a four-node flat finite element is more stable than the nonlinear implicit Newmark method. This structural dynamic algorithm is coupled with the unsteady vortex-ring method using a staggered technique. These procedures were used to obtain aeroelastic results of a nonlinear plate-type wing subjected to low speed airflow. It is shown that stable and accurate numerical solutions are obtained using the proposed fluid–structure interaction algorithm. Furthermore, it is illustrated that geometric nonlinearities lead to limit cycle oscillations.

ABSTRACT: The problem of the dynamic response of flat rectangular sandwich panels subjected to underwater and in-air explosions is analyzed. The study is carried out in the framework of a geometrically non-linear model of sandwich structures featuring anisotropic laminated face sheets and an orthotropic core, in conjunction with the unsteady pressure generated by an explosion. Effects of the core and of the orthotropy of its material, as well as those related to the ply-thickness, directional material property and stacking sequence of face sheets, geometrical non-linearities and of the structural damping ratio are investigated, and their implications upon the dynamic response are highlighted. To the best of the authors’ knowledge, the specialized literature addressing the dynamic response of sandwich structures to underwater and in-air explosions is rather scanty. This work is likely to fill a gap in the specialized literature on this topic.

and test structures within the laboratory. The tube is struck at one end by a steel projectile, with the test structure placed at the opposite end of the tube. Realistic exponentially decaying pressure pulses are generated in the water with peak pressures in the range 15–70 MPa and decay times ranging from 0.1 to 1.5 ms. The peak pressure and the pulse duration are independently adjusted by varying the projectile velocity and mass, respectively. The underwater shock simulator is used to investigate the one-dimensional fluid–structure interaction of sandwich plates with steel face sheets and an aluminium foam core. The degree of core compression is measured as a function of both the underwater shock impulse and the Taylor fluid–structure interaction parameter. Fully coupled finite element simulations agree well with the measurements while decoupling the fluid–structure interaction phase from the core compression phase within the finite element analysis leads to an under-prediction of the degree of core compression.

ABSTRACT: A discrete multi-layered cylindrical shell (DMC) consists of a thin inner cylindrical shell and helically cross-winding flat steel ribbons. The dynamic elastic response of such cylindrical shell under uniformly distributed pressure pulse is studied in this paper. Under the axisymmetric plane strain assumption, the solution of the problem is divided into two parts: a quasi-static part satisfying inhomogeneous stress boundary conditions and a dynamic part complying with homogeneous stress boundary conditions. The quasi-static part is determined by homogeneous linearity method and boundary conditions, and the dynamic part was worked out by means of finite Hankel transform and Laplace transform. The dynamic response of a DMC is compared with the response of monobloc cylindrical shell. Parametric analyses with the consideration of major influential factors, such as thickness ratio of the inner shell to that of the complete shell, material parameters and winding-angle, are discussed.

Enrico Ferri, Emilio Antinucci, Ming Y. He, John W. Hutchinson, Frank W. Zok and Anthony G. Evans,  

ABSTRACT: When sandwich panels with prismatic cores are impulsively loaded, the stresses imposed by the core on the front face, as well as those transmitted through the core govern the response metrics, especially the center displacement, resistance to tearing, and loads transmitted to the supports. This article presents a basic study of the dynamic response with emphasis on the I-core. A prior assessment revealed buckle waves induced because of inertial phenomena accompanying the rapid compression of the members. The development of these waves is an integral aspect of the dynamic response. One objective of this investigation is to ascertain the characteristics governing such waves in I-core configurations through a combined experimental and numerical study. A particular emphasis is on the influence of manufacturing imperfections in the core members on the formation and propagation of the buckles. A second goal is to examine the stresses associated with the dynamic compression of the core, again through a combined experimental and numerical investigation. The investigation is conducted for stainless steel I-core panels supported at the back face and subjected to a constant velocity at the front. Imperfections to be included in the numerical study have been ascertained by comparing buckle patterns with those found experimentally over the relevant velocity range. The simulations reveal that the stresses induced differ on the front and back faces. On the front they are higher and velocity dependent. On the rear they are velocity invariant and scale with the relative density and material yield strength. The duration of the stress pulses, which is essentially the same on both faces, scales linearly with the core height. It correlates with the time needed for bucklewaves to propagate through the core to the back face. After the pulse terminates, the core continues to compress at a stress level about an order of magnitude smaller.
ABSTRACT: This paper presents an analysis on attenuation of floating structures response to underwater shock. An explicit finite element approach interfaced with the boundary element method is used for the shock interaction problems. The attenuation effects of the floating structure response to underwater shock are deduced.

ABSTRACT: In combat operations, a warship can be subjected to air blast and underwater shock loading, which if detonated close to the ship can damage the vessel form a dished for hull plating or more serious holing of the hull. This investigation develops a procedure which couples the nonlinear finite element method with doubly asymptotic approximation method, and which considers the effects of transient dynamic, geometrical nonlinear, elastoplastic material behavior and fluid–structure interaction. This work addresses the problem of transient responses of a 2000-ton patrol-boat subjected to an underwater explosion. The KSF=0.8 is adopted to describe the shock severity. Additionally, the shock loading history along keel, the acceleration, velocity and displacement time histories are presented. Furthermore, the study elucidates the plastic zone spread phenomena and deformed diagram of the ship. Information on transient responses of the ship to underwater shock is useful in designing ship hulls so as to enhance their resistance to underwater shock damage.

ABSTRACT: Behaviour of plate specimens subjected to underwater explosion – a review”,

ABSTRACT: This paper reviews the previous work on structural optimization with frequency constraints. The sensitivity analysis, constraint approximations, and optimization algorithms are discussed in the context of frequency optimization. Frequency related issues and structural applications are presented by discussing the difficulties in designing structures with frequency constraints.

ABSTRACT: Undersea weapons, including torpedoes need to be designed to survive extreme loading conditions such as underwater explosions (UNDEX). In this work, a multidisciplinary optimization problem is solved for a lightweight torpedo model subjected to UNDEX. A torpedo configuration with least possible weight for a given level of safety from an explosion at a critical distance is obtained. The torpedo is modeled using both metallic and composite material models. The similitude relations are used to model the pressure wave resulting from an explosive, which is assumed as a spherical wave. The response of the composite flat plate is obtained prior to the torpedo for validating the analysis routine and determining the stress levels in each of the layers. The response of a composite lightweight torpedo model is also obtained and structural optimization is performed to achieve the minimum weight subject to the required safety levels. Similar analysis and optimization was performed for a stiffened metallic torpedo. The optimal designs for both models are compared and it is observed that the composite torpedo model is stronger and lighter than the metallic design when subjected to an UNDEX at a given standoff distance.

ABSTRACT: Nowadays, fluid-structure interaction problems are a great challenge of different fields in engineering and applied sciences. In civil engineering applications, wind flow and structural motion may lead to aeroelastic instabilities on constructions such as long-span bridges, high-rise buildings and light-weight roof structures. On the other hand, biomechanical applications are interested in the study of hemodynamics, i.e. blood flow through large arteries, where large structural membrane deformations interact with incompressible fluids. In the structural part of this work, a new methodology for the analysis of geometrically nonlinear orthotropic membrane and rotation-free shell elements is developed based on the principal fiber orientation of the material. A

ABSTRACT: Wind turbines are a real alternative for clean power generation aimed at reducing global warming and improving sustainable energy. To withstand wind forces, aerogenerators should be properly analyzed to ensure a good operation in the system lifetime. Several approaches can be established to perform analysis and design of this kind of structure. However, wind turbines have collapsed all around the world, and a reason for its failure is still being searched. In this paper, an engineering solution considering fluid structure interaction for wind turbines is presented, aiming to find why wind turbines collapse. Wind action is modelled through a stabilized fluid flow formulation, while the structure is solved with geometrically nonlinear shell elements with only translation degrees of freedom. In both cases (i.e., the modelling of the fluid as well as the structure), the finite element method is used to find a solution. The main result found in this study is the location of principal stresses in the structure due to dynamic wind action. It is concluded that most of the times failure of wind turbines will not occur in its base as it is usually believed.

ABSTRACT: From a structural perspective, the pressure hull is a significant structural component of underwater vehicles, to enable them to withstand environmental loadings such as hydrostatical pressure and underwater explosive loading. Hence, improving configuration design tends to be important for underwater vehicles. Applying a nonlinear FEM/DAA coupling procedure, which addresses the effects of transient dynamic, geometrical nonlinear, elastoplastic material behavior and the fluid structure interaction, this investigation examines the transient dynamic responses of a multiple intersecting spheres (MIS) deep-submerged pressure hull subjected to underwater explosion. The time histories of the wet-surface pressure, displacement, velocity, acceleration, von Mises stress and plastic strain are presented. Additionally, the deformed diagram and velocity distribution of MIS pressure hull are elucidated. The analytical results are valuable for designing novel pressure hulls to resist underwater explosion.

ABSTRACT: Significant reductions in the fluid structure interaction regulated transfer of impulse occur when sandwich panels with thin (light) front faces are impulsively loaded in water. A combined experimental and computational simulation approach has been used to investigate this phenomenon during the compression, of honeycomb core sandwich panels. Square cell honeycomb panels with a core relative density of 5% have been fabricated from 304 stainless steel. Back supported panels have been dynamically loaded in through thickness compression using an explosive sheet to create a plane wave impulse in water. As the impulse was increased, the ratio of transmitted to incident momentum decreased from the Taylor limit of 2, for impulses that only elastically deformed the core, to a value of 1.5, when the peak incident pressure caused inelastic core crushing. This reduction in transmitted impulse was slightly less than that previously observed in similar experiments with a lower strength pyramidal lattice core and, in both cases, was well above the ratio of 0.35 predicted for an unsupported front face. Core collapse was found to occur by plastic buckling under both quasistatic and dynamic conditions. The buckling occurred first at the stationary side of the core, and, in the dynamic case, was initiated by reflection of a plastic wave at the (rigid) back face sheet-web interface. The transmitted stress through the back face sheet during impulse loading depended upon the velocity of the front face, which was determined by the face sheet thickness, the magnitude of the impulse, and the core strength. When the impulse was sufficient to cause web buckling, the dynamic core strength increased with front face velocity. It rose from about 2 times the quasistatic value at a front face initial velocity of 35 m/s to almost 3 times the quasistatic value for an initial front face velocity of 104 m/s. The simulations indicate that this core hardening arises from inertial stabilization of the webs, which delays the onset of their buckling. The simulations also indicate that the peak pressure transmitted to a support structure from the water can be controlled by varying the core relative density. Pressure mitigation factors of more than an order of magnitude appear feasible using low relative density cores. The study reveals that for light front face sandwich panels the core strength has a large effect upon impulse transfer and the loading history applied to support structures.

ABSTRACT: Sandwich panel structures with thin front faces and low relative density cores offer significant impulse mitigation possibilities provided panel fracture is avoided. Here steel square honeycomb and pyramidal truss core sandwich panels with core relative densities of 4% were made from a ductile stainless steel and tested under impulsive loads simulating underwater blasts. Fluid-structure interaction experiments were performed to (i) demonstrate the benefits of sandwich structures with respect to solid plates of equal weight per unit area, (ii) identify failure modes of such structures, and (iii) assess the accuracy of finite element models for simulating the dynamic structural response. Both sandwich structures showed a 30% reduction in the maximum panel deflection compared with a monolithic plate of identical mass per unit area. The failure modes consisted of core crushing, core node imprinting/punch through/tearing and stretching of the front face sheet for the pyramidal truss core panels. Finite element analyses, based on an orthotropic homogenized constitutive model, predict the overall structural response and in particular the maximum panel displacement.

ABSTRACT: The dynamic response of deformable structures subjected to shock load and cavitation reload has been simulated using a multiphase model, which consists of an interface capturing method and a one-fluid cavitation model. Fluid–structure interaction (FSI) is captured via a modified ghost fluid method (Liu et al. in J Comput Phys 190: 651–681, 2003), where the structure is assumed to be a hydro-elasto-plastic material if subjected to a strong shock load. Bulk cavitation near the structural surface is captured using an isentropic model (Liu et al. in J Comput Phys 201:80–108, 2004). The integrated multiphase model is validated by comparing numerical predictions with 1D analytical solutions, and with numerical solutions calculated using the cavitation acoustic finite element (CAFÉ) method (Sprague and Geers in Shocks vib 7:105–122, 2001). To assess the ability of the multiphase model for multi-dimensions, underwater explosions (UNDEX) near structures are computed. The importance of cavitation reloading and FSI is investigated. Comparisons of the predicted pressure time histories with different explosion center are shown, and the effect on the structure is discussed.

ABSTRACT: In this paper, the acoustic scale effects and boundary effects for the similitude model of underwater complex shell-structure are investigated. The similitude conditions and relations between the similitude model and its prototype were studied in the references. This paper investigates the acoustic scale effects for the similitude model, which are influenced by loss factor, shear and rotatory inertia. At the same time, the boundary effects which are influenced by surface sound reflection are investigated in the experiment of similitude model. The results show that the acoustic scale effects may be controlled with model designing, the boundary effects can be controlled with experimental designing between the similitude model and its prototype.

ABSTRACT: Clamped circular copper plates have been subjected to exponentially decaying underwater blast waves with peak pressures in the range 10 MPa to 300 MPa and decay constants varying between 0.05 ms to 1.1 ms. The deformation and failure modes were observed by high-speed photography. For the thin plates considered in this study, the failure modes were primarily governed by the peak pressures and were reasonably independent of the blast wave decay constant. Three modes of deformation and failure were identified. At low pressures, the plates undergo bending and stretching without rupture (mode I). At intermediate pressures a range of tensile tearing modes were observed, from petalling failures to tearing at the supports with increasing blast pressures. These tearing modes are referred to as mode II failures. At the highest pressures investigated here, the plate tears at the supports in a manner that is reminiscent of a shear-off failure. This failure is labeled as mode III. Scanning electron micrographs of the failure surfaces showed that in all cases, the local failure mechanism was tensile necking. Finite element (FE) simulations employing a local shear failure criterion are used to model the rupture of the material. Appropriately calibrated FE models capture all failure modes with sufficient fidelity.

ABSTRACT: A viscous flow model was developed to investigate the stability of a rotating cylindrical shell containing axial flow because the inviscid model was shown to be inadequate due to singularities in the solution. It was found that the stability of the system is very sensitive to the treatment of the shell-fluid interface and that a small rate of rotation tends to stabilise the system.

ABSTRACT: This paper is concerned with the nonlinear dynamics and stability of thin circular cylindrical shells clamped at both ends and subjected to axial fluid flow. In particular, it describes the development of a nonlinear theoretical model and presents theoretical results displaying the nonlinear behaviour of the clamped shell subjected to flowing fluid. The theoretical model employs the Donnell nonlinear shallow shell equations to describe the geometrically nonlinear structure. The clamped beam eigenfunctions are used to describe the axial variations of the shell deformation, automatically satisfying the boundary conditions and the circumferential continuity condition exactly. The fluid is assumed to be incompressible and inviscid, and the fluid–structure interaction is described by linear potential flow theory. The partial differential equation of motion is discretized using the Galerkin method and the final set of ordinary differential equations are integrated numerically using a pseudo-arclength continuation and collocation techniques and the Gear backward differentiation formula. A theoretical model for shells with simply supported ends is presented as well. Experiments are also described for (i) elastomer shells subjected to annular (external) air-flow and (ii) aluminium and plastic shells with internal water flow. The experimental results along with the theoretical ones indicate loss of stability by divergence with a subcritical nonlinear behaviour. Finally, theory and experiments are compared, showing good qualitative and
reasonable quantitative agreement.

“Effect of geometric imperfections on nonlinear stability of cylindrical shells conveying fluid”, ENOC 2008, Saint Petersburg, Russia, June, 30-July, 4 2008

ABSTRACT: Circular cylindrical shells conveying subsonic flow are addressed in this study; they lose stability by divergence when the flow speed reaches a critical value. The divergence is strongly subcritical, becoming supercritical for larger amplitudes. Therefore the shell, if perturbed from the initial configuration, undergoes severe deformations causing failure much before the critical velocity predicted by the linear threshold. Both Donnell’s nonlinear theory retaining in-plane displacements and the nonlinear Sanders-Koiter theory are used for the shell. The fluid is modelled by potential flow theory. Geometric imperfections are introduced and fully studied. Non-classical boundary conditions are used to exactly simulate the conditions of the experiments performed. Comparison of numerical and experimental results is performed.

ABSTRACT: This paper investigates the nonlinear dynamic response of a shallow sandwich shell subject to blast loading with consideration of core compressibility. The shallow shell consists of two laminated composite or metallic face sheets and an orthotropic compressible core. Experimental results and finite element simulations in literature have shown that the core exhibits considerable compressibility when a sandwich panel is subjected to impulse loading. To address this issue properly in the analysis, a new nonlinear compressible core model is proposed in the current work. The system of governing equations is derived by means of Hamilton’s principle in combination with the Reissner–Hellinger’s variational principle. The analytical solution for the simply supported shallow shell is formulated using an extended Galerkin procedure combined with the Laplace transform. Numerical results are presented. These results demonstrate that this advanced sandwich model can capture the transient responses such as the stress shock wave effect and the differences in the transient behaviors of the face sheets and the core when a sandwich shadow shell is subjected to a blast loading. However, in the steady state dynamic stage, all the displacements of the face sheets and the core tend to be identical. This model can be further used to study the energy absorption ability of the core and the effects of different material and geometrical parameters on the behaviors of sandwich structures subject to blast loading.

ABSTRACT: This paper deals with the human head response to a sudden motion without direct contact with another solid object, i.e. to non-contact impact. A computational simulation approach is presented for this study, which is accomplished by the integration of a coated articulated total body (ATB) model with a finite element (FE) head model. The present approach includes two major aspects: one is to simulate the sudden motion of the human head with the whole body by means of the ATB model; and the other is to predict the head deformation and stress induced by the sudden motion through using the FE head model. The agreement between the simulation results and the published experimental data [Wismans J, Hermans J. MADYMO 3D simulations of hybrid III dummy sled tests. In: Backailis SH, Mertz HJ, editors. Hybrid III: the first human-like crash test dummy, SAE PT-44, 1994. p. 735-49; Nahum AM, Smith R, War CC. Intracranial pressure dynamic during head injury. In: 21st Stapp car crash conference proceedings, SAE 770922; 1977] is obtained. The intracranial pressure response and the head stress response are then predicted using the present approach. The correlation between the head motion and the brain stresses are also explored. In addition, the head injury induced by the non-contact impact is evaluated.

ABSTRACT: A new concept is presented for modeling the dynamic interaction between an acoustic fluid and an elastic structure. The coupling of this multiphysics system is done by inserting a kinematic interface frame between the fluid and the structure, and using node-collocated Lagrange multipliers to connect the frame to each subsystem. The time-domain response analysis is performed by a partitioned analysis procedure. The main advantages of this localized Lagrange multiplier (LLM) primal-dual coupling method are: complete localization...
of the structure and fluid subsystems, elimination of the conventional predictor in the partitioned time integration method, and the ability to accommodate non-matching meshes. The standard Newmark time integrator is used on both the fluid and structure models. It is shown that if the integrator is A-stable and second-order accurate for a monolithic treatment, it retains those properties for both Mortar and LLM partitioned solution procedures. Infinite and finite piston problems are used to explain and verify the methodology. A sequel paper under preparation presents and discusses a set of benchmark and application examples that involve the response of existing dams to seismic excitation.

“Nonlinear-inelastic seismic performance of water storage tanks”, The 14th World Conference on Earthquake Engineering, October 12-17, 2008, Beijing, China

ABSTRACT: This paper evaluates the seismic response of ground-level cylindrical steel water storage tanks, which were designed under the American Water Works Association standards for steel tanks. Three tank sizes were selected to represent different height to radius ratios. All tanks are anchored on concrete ring-wall foundations. Nine earthquake time history records were used to develop response spectrums as input for design level ground motion. A combined fluid-structure finite element model was developed for each of the tank geometries. The computer models were run using linear elastic and nonlinear inelastic model property assumptions. Results of this study show the substantial variation of values in base shear and overturning moment depending on the seismic inputs and modeling assumptions used. The ratios of base shear between linear elastic and nonlinear properties ranged from 1.0 to 3.1, and overturning moment values ranged from 1.0 to 3.0, which are mostly smaller or equal to the design standard reduction R-factored value of 3.0 for anchored tanks.

ABSTRACT: Measurements of acceleration and pressure together with high-speed imaging have been used to study the interaction of an underwater explosion with a nearby steel cylinder. Variation of the initial separation between the cylinder and explosive charge generated different cases of interaction in which the response of the cylinder to the shock wave, the bubble pulse wave, water jetting and bubble collapse could be studied. Shock wave loading generated a significant response in all cases. The pressure wave from the pulsating bubble was a less significant load, generating a peak velocity about half that caused by the shock wave. However the collapse of the bubble onto the cylinder was found to be the most severe structural load, generating a peak velocity almost twice that caused by the shock wave and causing significant plastic deformation.

ABSTRACT: Based on the potential flow theory, the boundary element method (BEM) is applied to calculate the dynamics of an underwater explosion bubble near boundaries, and in conjunction with the finite element method (FEM) it is employed to compute the interaction between a bubble and an elastic–plastic structure. A complete 3D underwater explosion bubble dynamics code is developed; the simulated results compare well with an underwater explosion experiment. With this code, the interactions between an underwater explosion bubble and elastic–plastic structures such as a flat plate, a cylinder and other simple structures are calculated and analyzed. Besides, the damages caused by the after flow, pulsating pressure, and jetting load on the structures are also calculated, with or without a free surface. From the time history of the pressure and stress of the structure, it can be observed that the stress reaches its maximum value when the bubble collapses, which proves that the pressure and jet impact induced by the collapse of the bubble can result in severe damage to the structure. In particular, the 3D analysis code is applied to some engineering problems, for example it is used on a surface ship to study the interaction between a bubble and a complex elastic–plastic structure. Under the bubble load, the low-order eigenfrequency of the ship is aroused usually, leading to the so-called ‘whipping’ effect, because the pulsating frequency of the bubble ‘matches’ the low-order eigenfrequency of the ship. The ship moves up and down with the expansion and collapse of the bubble respectively. Meanwhile, the power of the bubble generated by a near-field underwater explosion in short range is discussed, and some important conclusions which can be applied to project application field are drawn.

ABSTRACT: The design of submarines has continually evolved to improve survivability. Explosions may induce local damage as well as global collapse to a submarine. Therefore, it is important to realistically estimate the possible damage conditions due to underwater explosions in the design stage. The present study applied the Arbitrary Lagrangian–Eulerian (ALE) technique, a fluid–structure interaction approach, to simulate an underwater explosion and investigate the survival capability of a damaged submarine liquefied oxygen tank. The Lagrangian–Eulerian coupling algorithm, the equations of state for explosives and seawater, and the simple calculation method for explosive loading were also reviewed. It is shown that underwater explosion analysis using the ALE technique can accurately evaluate structural damage after attack. This procedure could be applied quantitatively to real structural design.

ABSTRACT: The fluid-structure interaction simulation of shock-loaded thin-walled structures requires numerical methods that can cope with large deformations as well as local topology changes. We present a robust level-set-based approach that integrates a Lagrangian thin-shell finite element solver with fracture and fragmentation capabilities into an Eulerian Cartesian fluid solver with embedded boundary and mesh adaptation capability. As main computational applications, we consider the plastic deformation and rupture of thin plates subjected to explosion and piston-induced pressure waves in water.

ABSTRACT: Model based on discrete reinforced rectangular section stiffeners for example, idealized fluid as incompressible ideal potential flow, a reasonable simplification underwater explosion shock wave generated by the load, to consider the impact of the hydrodynamic pressure stiffened cylindrical The theoretical analysis of the shell structure of the model, and the search for effective analysis calculation method, to explore the structure by the underwater explosion shock loads power response and dynamic buckling improve the impact resistance of underwater submersible structure provides some meaningful conclusions. Work of this paper are mainly the following aspects: First, a comprehensive review summarizes the free vibration of stiffened plate and shell structures under impact loading dynamic response and dynamic buckling focus stiffened cylindrical shell by the underwater explosion shock loads The dynamic characteristics of commence comments. The use of commercial finite element software MSC.DYTRAN, simulated spherical TNT charge in the underwater explosion, focus on using two coupling methods (General coupling and ALE) stiffened cylindrical shell underwater spherical explosive load of TNT kits under vibration and dynamic response characteristics, and the results with the experimental results in the relevant references compared two basic agreement. Ring stiffened cylindrical shell discretized into cylindrical shell and reinforced ribs and both rigidly connected to the contact the casing - ribs systems, taking into account the casing shear deformation and rotational inertia as well as reinforced ribs tensile, bending and shear deformation, Hamilton variational principle derived system equations of motion. Expand the displacement as a Fourier series form by the Galerkin method to displacement Fourier coefficients in the form dynamic buckling control equations using a fourth-order Runge-Kutta method calculated stiffened cylindrical shell in the underwater explosion shock loads under the action of the dynamic response. Focused on the hydrodynamic pressure, hydrostatic pressure, reinforced rib geometry parameters, the thickness of the shell, and the Fourier series, the number of items on the calculation results verify some common conclusions. And also discussed the free vibration problem of stiffened cylindrical shells under water. On the basis of the above analysis, taking into account large deformation and the impact of the initial defect stiffened cylindrical shell underwater explosion loads, nonlinear response, summed up some useful conclusions. Followed by analysis of ring stiffened cylindrical shell underwater explosion loads elastoplastic dynamic response. Elastoplastic constitutive relation given by Mises yield condition and isotropic hardening incremental theory. With the increment value (in the time domain using a fourth-order Runge-Kutta method) method to analyze the elastoplastic behavior of stiffened cylindrical shell. Analyzed the impact of the ring to the reinforced ribs, uniform radial external pressure and strain rate sensitivity and other factors on structural elastoplastic dynamic response. Then stiffened cylindrical shell in the underwater explosion shock - Solid Impact nonlinear dynamic buckling under a combined load used the BR criterion to determine the structure of the critical buckling load, compare the structure, respectively, in the axial flow and axial flow - solid impact loading, underwater explosive shock alone and two loads under the combined effects of buckling mode, the critical load, focuses on the relationship between the two directions of the critical load, hoop reinforced rib stiffened cylindrical shell structure Dynamic buckling behavior and anti-axial impact buckling capacity to draw meaningful conclusions. And also with the BR Standards and Southwell are two ways to calculate the radial shock loads Dynamic buckling load stiffened cylindrical shell in the underwater explosion. The power of the geometrical parameters, material hardening parameters of stiffened cylindrical shell structure critical buckling load.

ABSTRACT: Underwater explosion and its effect on structures including flat plate, cylindrical shell and torpedo shell were studied in this dissertation by using commercial software AUTODYN, ABAQUS and LS-DYNA. The main work includes: (1) Numerical simulation of underwater explosion process, (2) The re-exploitation of ABAQUS based on Taylor’s plate theory and the first-order doubly asymptotic approximation and its application, (3) Numerical study of dynamic response of cylindrical shell subjected to deep water blast wave, (4) The modification of the simulation method of LS-DYNA to calculate far-field underwater shock wave, (5) The elementary analysis of the terminal effect of torpedo-damaging by underwater shock waves, (6) Numerical simulation of the dynamic response of torpedo shell structure subjected to near-field and far-field
underwater shock waves. Chapter 1: The research content in this dissertation, as well as the research method and background, were concisely presented, and the evolution of relative research, as well as the software of numerical simulation and the method to validate the calculation results, were given. Chapter 2: Underwater explosion shock wave and bubble pulse were simulated by using the hydrocode AUTODYN. By comparing calculation results with empirical formulas, theoretical formulas and experimental results, one can conclude that AUTODYN can simulate much of the important physics of underwater explosion, and the suggestion for the engineering application of AUTODYN was given. Chapter 3: Based on Taylor’s plate theory and the first-order doubly asymptotic approximation (DAA) without considering low-frequency response, a simple and practical method has been presented to simulate the high-frequency dynamic plastic response of basic structure including flat plate and cylindrical shell subjected to underwater explosion shock waves without modeling the fluid field. Commercial finite element code, ABAQUS, was used to conduct this simulation. In order to validate this method, two examples including a fixed flat plate and a free cylindrical shell, all subjected to underwater explosion shock waves, were simulated by the method, and the simulation results are in good agreement with experiment results. Chapter 4: Numerical investigation was carried out on a cylindrical shell subjected to underwater explosion shock waves in deep water by using both static state analysis and dynamic analysis via ABAQUS software package. The influence of the depth of the cylindrical shell lies, orientation of the explosion and prestress were identified, and the breakage of the cylindrical shell in deep water was also studied. Chapter 5: The elementary analysis of the terminal effect of torpedo-damaging by underwater shock waves was presented, and a simple model to analyze this problem was given. Then the main factors to influence the terminal effect were identified, and an idea was given to direct the following numerical study. Aim at the problem that the peak pressure of shock waves induced by far-field underwater explosion are smaller than actual magnitude when using LS-DYNA to simulate underwater explosion, a equivalent mass method which had been validated was presented to solve it. After this, the dynamic response of a lightweight torpedo shell structure subjected to shock waves induced by far-field underwater explosion was simulated by LS-DYNA, and influence of the torpedo insides and shock environment of the torpedo shell structure were studied. The damage mechanism of torpedo shell subjected to underwater explosion shock waves was simulated by using LS-DYNA. The damage mechanism of the torpedo shell, as well as shock environment and vulnerability of the different torpedo cabin shell, were investigated. Chapter 6: The main conclusions and suggestions for the following investigation are given.

ABSTRACT: The underwater explosion needs considering five parts: shock wave, cavitations and bubble, jet, fluid-solid coupling phenomenon, the dynamic response of structure. In this paper, the flow field of the bubble pulsation was solved by using the theory analysis and numerical simulation method under near the underwater explosion. The response of the plate under the bubble pulsation pressure effect was analyzed. Connection the underwater acoustic energy and explosion shock wave, by using the fluid-solid coupling method the failure of cylindrical shell and the vibration response of cylinder under the far fielded directional shock wave was researched. For the underwater acoustic energy technology attacking the near ship target provides basis. The bubble produced by near underwater explosion was analyzed. According to the one dimensional incompressible fluid unsteady motion theory, considering addition the work by the virtual force, the existing law equation of bubble pulsation underwater explosion was improved. Comparison analysis the calculation results with the experimental values, considering the addition of the virtual force, the radius, period and velocity of the calculation bubble pulsations by the theory formula were more anatomists with the practical condition. Further improving the law equation of bubble pulsation pressure distribution, the addition effect of the bubble energy, the results were more according with the practical condition than previous analysis. Under the near bubble pulsation, the bubble pulsation load was treatment for spherical wave. Then the clamped circular plate was affected by it. By the Ritz equation the deflection formula of the circular plate was calculated. The income data were fitted a unified formula. Based on the deflection change graph, the center of circular plate was most easily failure. The boundary of circular plate also possibly was damaged under the condition of the thin plate. According to the features between the underwater acoustic energy technology and explosion, the acoustical parameters were converted into the form of explosion shock wave pressure. The strength analysis of cylindrical shell was calculated under the effect of the shock wave. According to the feature of the far field shock wave, it
was assumed plane wave to directly apply on a little layer water surface nearby the shell. Using the fluid-solid coupling analysis method of LS-DYNA, the strength of the cylindrical shell was simulated calculated under effect of the underwater directional acoustic energy at 30m. Over 280db sound source grade of the underwater directional shock wave could be certain failure to the cylindrical shell at 30m. The dynamic response of cylinder was simulated under the effect of underwater directional acoustic energy at 100m. When the cylinder was affected by the large energy shock wave pressure, the response of acceleration was rapidly reached the peak which was large and the waveform was steep. However, due to the cylinder coupling with water the vibration energy was quickly dissipated. When the acceleration reached 30g, the internal components may be failure. If according to this standard test the failure situation was caused by the vibration of cylinder. When the sound source grade ≥ 280dB, the internal components maybe could be damaged because of the vibration. The theory and numerical basis were provided by the contents in this paper for the underwater directional acoustic energy technology attacking the near ship target.

Tim Dunbar and Dave Whitehouse (1888 Brunswick Street, Suite 400, Halifax, NS, Canada B3J 3J8) “Simulation of structural failure from contact underwater explosions”
ABSTRACT: A numerical method for performing large-deformation two-way coupled fluid-structure interaction simulations has been developed to model a wide class of problems in which structural response significantly influences subsequent fluid flow, through motion-induced cavitation, structural failure or both. We demonstrate the suitability of the approach to such events by applying our method to the early-time response of plates to contact and near-contact underwater explosions in three dimensions. The plates exhibit a variety of behaviors including petalling failure with venting of explosive products through the resulting holed plates. The deformation and failure patterns of the plates are compared with experimental data from trials performed by Defense Research Development Canada at Suffield.

Serguei Iakovlev (Dalhousie University, Halifax, Nova Scotia, Canada) “Modeling shell-shock interaction in a multi-fluid environment”
ABSTRACT: A fluid-filled submerged cylindrical shell is considered for the most general case of contact with fluid, i.e., when the internal and external fluids are different. It is shown that the interaction in this case is very different from the case of two identical fluids. Specifically, it is demonstrated that the response of the system is much more complex in terms of the fluid-structure interaction effects, and that a wider variety of shock wave reflection phenomena is observed. The ratio of the acoustic speeds in the internal and external fluids is shown to be the single most important parameter determining the main features of the interaction. Depending on the value of the ratio, four qualitatively different regimes of interaction are shown to exist. Each regime has its unique dynamic features of which the most notable is the possibility of observing different reflection-focusing sequences for the pressure wave inside the shell. The practical relevance of the fluid-structure interaction effects observed is discussed. This is a joint work with Garrett Dooley, Bryan MacDonald and Jonathan Gaudet.

Cedric Leblond and Jean-Francois Sigrist (Service Technique et Scientifique, DCNS Propulsion / LEPTIAB, Universite de La Rochelle) “Semi-analytical methods for the study of transient fluid-structure interaction problems”
ABSTRACT: We study semi-analytical methods related to the effects of highly transient loads on
underwater vehicles. Firstly, simple fluid-structure interaction models are derived so as to highlight the physical phenomena occurring in this problem. More precisely, interactions between circular thin shells or elastic structures and the radiated field by an underwater explosion are considered. The approach is based on the classical methods of Laplace transform in time, Fourier series expansions and separation of variables in space. Secondly, an extension of this approach is proposed for more complex geometries. It is based on Laplace transform in time, in vacuo eigenvector expansion with time-dependent coefficients for the structural dynamics and boundary-integral formulation for the fluid. The projection of the fluid pressure on the in vacuo eigenvectors leads to a fully coupled system involving the modal time-dependent displacement coefficients, which are the problem unknowns. They are simply determined by matrix inversion in the Laplace domain. This fluid-structure numerical method is exact in the sense that classical early-time or doubly asymptotic approximations are not made. This appears to be a versatile approach which can be efficiently and extensively used for design purposes, once part of the numerical resolution has been performed one time for a given geometry.

Julie Young (Princeton University) “Numerical Investigation of Shock and Blast Loads on Composite Marine Structures”

ABSTRACT: A strongly coupled 2D/axisymmetric Eulerian–Lagrangian numerical solver is presented for the modeling of shock and blast loads on composite marine structures. An overview of the numerical formulation is given for the compressible multiphase fluid, the generalized continuum solid, and the fluid-fluid and fluid-solid interface coupling methodology using modified versions of the ghost fluid method. The resulting strongly coupled Eulerian–Lagrangian solver is able to efficiently capture nonlinear fluid-structure and shock-bubble interactions involving strong shocks, gas bubble dynamics, cavitation inception and collapse, and complex stress and deformation fields of anisotropic, composite marine structures. Analytical, numerical, and experimental validation studies are shown. The objective of this work is to use the newly developed coupled Eulerian–Lagrangian method to study the transient response of composite marine structures subject to shock and blast loads. Special attention is given to quantify the influence of surface and core material elasticity/plasticity, boundary conditions, surface curvature, and strain-rate dependency on the fluid-structure interaction response caused by planar shocks and underwater explosions. The goal is to develop parametric curves that can assist the design of general composite structures subject to shock and blast loads, and to explore potential shock mitigation strategies.

ABSTRACT: Circular cylindrical shells conveying incompressible flow are addressed in this study; they lose stability by divergence when the flow velocity reaches a critical value. The divergence is strongly subcritical, becoming supercritical for larger amplitudes. Therefore the shell, if perturbed from the initial configuration, has severe deformations causing failure much before the critical velocity predicted by the linear threshold. Both Donnell's non-linear theory retaining in-plane displacements and the Sanders–Koiter non-linear theory are used for the shell. The fluid is modelled by potential flow theory but the effect of steady viscous forces is taken into account. Geometric imperfections are introduced and fully studied. Non-classical boundary conditions are used to simulate the conditions of experimental tests in a water tunnel. Comparison of numerical and experimental results is performed.

ABSTRACT: In this paper, a numerical model based on the potential flow theory is established to simulate the interaction of a gas bubble with a nearby wall. The time-integration boundary integral method is used to solve the dynamics of a gas bubble. With this method the numerical calculations show an excellent agreement with
the experimental data. Employing the numerical code based on the presented algorithm, the dynamics of a gas bubble close to a rigid wall is investigated systematically, especially the relationship between various characteristic parameters and the Bjerknes effect due to the presence of a nearby wall. It is found that Blake's criterion, which is usually used to predict the direction of the bubble jet, has a great degree of accuracy for the bubble relatively far away from the wall and bubble near a wall, there is a significant error, attributed to its simplifications and assumptions. Further studies show that an oblique jet will be formed when a bubble close to an inclined wall collapses, direction and width of which have a close relationship with the characteristic parameters used to characterize the bubble. For the bubble near a horizontal wall, a liquid jet pointing directly to the wall is developed generally when the Bjerknes attraction and buoyancy are in the same direction; and at the same time, if the Bjerknes attraction is in the opposite direction of buoyancy, the direction of the jet will depend on a criterion. Then the interaction of gas bubble between complicated walls of some a submarine is also studied, which shows the most dangerous induced loading condition of structure in water, and the evidently effects of bubble jet on loading. The special phenomena mentioned above have a great significance for the further study on the interaction of the bubble with its boundaries.

ABSTRACT: How to moderate ship the damages caused by the underwater explosions is of great interest to the modern ship designers. This investigation explores the protective effects of a layer of rubber sandwich with the square honeycomb core coated onto ship hull. Two slender steel scaled ship models were manufactured and tested. One model was coated with a layer of rubber coating while the other kept intact. A series of comparative tests were carried out to comprehend the dynamic performance of the protective layer when both shock wave and bubble pulse loading were considered. Modal characteristics of both models were measured firstly and then live UNDEX tests were made on the free floating ship models. The acceleration and strain peaks were selected as the major comparative criterions. The free field and wall pressure were also monitored. Detailed discussions on test results show that the protective rubber layer is capable of moderating damage of the ship body caused by shock wave while not very effective in reducing the whipping damage excited by bubble pulse.

ABSTRACT: The paper deals with numerical methodologies to model and study the structural resistance of submarine hull against explosions, where fluid and solid phenomena interact. Explosion Crack Starter Tests (ECST), which are a standard procedure to study submarine materials and weldments with respect to blast loading, are modelled using an explicit FE code that solves Fluid/Structure (F/S) interactions within the same computation. The proposed numerical methods aim at computing the structural response of a target subjected to sequential explosions. Numerical results are compared to the corresponding explosion tests (ECST) performed by DGA (French Ministry of Defence).

ABSTRACT: The high imperfection sensitivity of cylindrical shells under static compressive axial loads is a well-known phenomenon in structural stability. On the other hand, less is known of the influence of imperfections on the nonlinear vibrations of these shells under harmonic axial loads. The aim of this work is to study the simultaneous influence of geometric imperfections and an axial fluid flow on the nonlinear vibrations and instabilities of simply supported circular cylindrical shells under axial load. The fluid is assumed to be non-viscous and incompressible and the flow to be isentropic and irrotational. The behavior of the thin-walled shell is modeled by Donnell's nonlinear shallow-shell equations. It is subjected to a static uniform compressive axial preload plus a harmonic axial load. A low-dimensional modal expansion, which satisfies the relevant boundary and continuity conditions, and takes into account all relevant nonlinear modal interactions observed in the past in the nonlinear vibrations of cylindrical shells with and without flow is used together with the Galerkin method to derive a set of eight coupled nonlinear ordinary differential equations of motion which are, in turn, solved by the Runge–Kutta method. The shell is considered to be initially at rest, in a position corresponding to a pre-buckling configuration. Then, a harmonic excitation is applied and conditions for parametric instability and dynamic snap-through are sought. The results clarify the marked influence of geometric imperfections and fluid flow on the dynamic stability boundaries, bifurcations and basins of attraction.

ABSTRACT: One of the major problems confronted by the designer of submersibles is to minimize the weight of the pressure hull for increasing the payload of a crew and necessary equipment and to simultaneously enhance the strength of the pressure hull for withstanding hydrostatic pressure, underwater explosive loading and other environmental loading. Hence, this paper presents the optimal design of a small-scale midget submersible vehicle (MSV) pressure hull with a ring-stiffened cylinder and two hemispherical ends subjected to hydrostatic pressure, using a powerful optimization procedure combined the extended interior penalty function method (EIPF) with the Davidon-Fletcher-Powell (DFP) method. According to the above optimum design results, we built up midget submersible vehicle finite element model. Then, the coupled acoustic-structural arithmetic from the widely used calculation program of the finite element – ABAQUS, was used to simulate and analyze the transient dynamic response of a midget submersible vehicle pressure hull that experiences loading by an acoustic pressure shock wave resulting from an underwater explosion (UNDEX). The analytical results are presented which will be used in designing stiffened optimum submersible vehicle so as to enhance resistance to underwater shock damage.

ABSTRACT: A submerged fluid-filled circular cylindrical shell subjected to a shock wave propagating in the external fluid is considered. The study focuses on a number of acoustic and structural effects taking place during the interaction. Specifically, the influence of the acoustic phenomena in the fluid on the stress–strain state of the shell is analysed using two different visualization techniques. The effect that the parameters of the shell have on the internal acoustic field is addressed as well, and the ‘shock transparency’ of various shells is discussed. Special attention is paid to the analysis of the contribution of the terms in the shell equations representing bending stiffness, and the limits of applicability of the membrane theory of thin shells are discussed in the fluid–structure interaction context. The possibility of cavitation in the internal fluid is investigated, and the effect that cavitation could have on the structural dynamics of the shell is discussed. The
The present paper is a follow-up of the author's earlier study of the interaction between fluid-filled cylindrical shells and external shock waves.

**ABSTRACT:** A submerged fluid-filled cylindrical shell subjected to an external shock wave is addressed for the most general case when the internal and external fluids have different properties. Three distinctly different scenarios of interaction are identified depending on the parameter $\zeta$ defined as the ratio of the acoustic speed in the internal fluid to that in the external one. The first scenario corresponds to the values of $\zeta$ below unity, and it can follow two sub-scenarios that exhibit qualitatively different focusing and reflection sequences, with the transition between the sub-scenarios occurring at $\zeta \approx 0.52$. The second scenario, $\zeta = 1$, corresponds to the relatively well-studied case of two identical fluids, yet some interesting, previously unreported effects are observed for such $\zeta$ as well. The third scenario corresponds to the values of $\zeta$ above unity, and it also exhibits a number of unique features of the wave propagation and reflection. The dynamics of the complete internal-external field is visualized and analyzed for the three scenarios, with the emphasis on both the theoretical significance of the effects observed and their practical implications.

**ABSTRACT:** Ambient temperature underwater explosion bulge test is simulated using ANSYS/LS-DYNA. Elastic and inelastic numerical experiments are carried out. Inelastic prediction is validated with a physical experimental data. Terminal strain to fracture is established. A methodology is thus arrived at for carrying out the material qualification for explosive loading using numerical simulation.

**ABSTRACT:** The response of a lightweight torpedo when subjected to an underwater explosion (UNDEX) is an important criterion for multidisciplinary design. This paper investigates the effect of structural stiffeners on the performance of a lightweight torpedo. The finite element package ABAQUS was used to model the UNDEX and the fluid–structure interaction (FSI) phenomena, which are critical for accurate evaluation of torpedo stress levels. The pressure wave resulting from an underwater explosion was modeled using similitude relations and it was assumed to be a spherical wave. Various explosive weights and explosion distances were explored to determine the critical distance both for an unstiffened and a stiffened torpedo. Once it was established that the stiffened torpedo performed better under explosive pressure loads, various configurations were studied to determine the optimal number of ring and longitudinal stiffeners. A final configuration was obtained for the torpedo that had minimum weight and was least sensitive to small manufacturing variations in
the dimensions of the stiffeners. This paper presents details of the torpedo and fluid models and the finite element analysis method for FSI.

ABSTRACT: In order to evaluate the strength and comparability of impulsive environment of model and practical structure in the water when subjected to underwater explosion, a new shock factor based on energy acting on the structure is presented to describe the loading of underwater explosion. To test the validity of this new factor, numerical experiments of double stiffened cylindrical shells are carried out a series of cases designed by the new factor and two other standard shock factors respectively. The results of the cases designed by the new factor indicate that the kinetic energy, potential energy and shock response spectrums of the structures agree well with each other in different cases designed by the equal new shock factor. However, the results of the cases designed by the two other standard shock factors are rather diverse. The analysis considers that the old shock factors do not take the spherical characteristics of shock wave front and relative position between detonation and structure into account, which can hardly reflect the similarity of underwater explosion loadings. The new shock factor can make up for such limitations.

ABSTRACT: This study investigated the linear and nonlinear dynamic responses of three cylindrical shell structures subjected to underwater small charge explosions in a 4m x 4m water tank. The dimensions of the cylindrical shell structures were 90 cm x 30 cm x 1mm (length x diameter x thickness). Both ends of the cylindrical shell were mounted with thick plates to provide support and create an enclosed space. The three cylindrical shell structures were unstiffened, internally stiffened and externally stiffened. The experiments involving the dynamic response of cylinders subjected to underwater explosion (UNDEX) were performed under different standoff distances, varying from 210 cm to 35 cm. A small quantity of explosives was used to generate the shock loading. The plastic deformation of the cylindrical shell was observed at a standoff distance of less than 50 cm. Other conditions were tested to examine cylinder linear response. Dynamic analyses were performed for the experimental model using FEM and compared with the test results. The acceleration and dynamic strains of cylindrical shells obtained from the experiment were compared with those obtained by FE analysis. Finally, problems related to small-scale UNDEX experiments performed in small water tanks were analyzed.

ABSTRACT: The problem of the transient vibration of an elastic laminated composite cylindrical shell with infinite length exposed to an underwater shock wave is solved approximately. The linear acoustic plane wave assumption and Sanders thin shell theory are adopted. The reflected-afterflow virtual-source (RAVS) procedure is used to model the fluid–structure interaction involved during the underwater shock event. For the validity of the present analysis, the response of a laminated cylindrical shell under step plane wave is first analyzed and compared with the numerical solution available in the literature. Detailed numerical results for the transient responses of the shells under an exponentially decaying underwater shock wave are presented, and the influences of fiber angle, shell radius and thickness upon the dimensionless radial velocity, mid-surface strain, 0th mode radial displacement and 1st mode radial velocity of the shells, are investigated.
ABSTRACT: Plates form one of the basic elements of structures. Land-based structures may be subjected to air blast loads during combat environment or terrorist attack, while marine structures may be subjected to either air blast by the attack of a missile above the water surface or an underwater explosion by the attack of a torpedo or a mine or a depth charge and an aircraft structure may be subjected to an in-flight attack by on-board explosive devices. Furthermore, gas explosion occurs in offshore installations and industries. This review focuses on the phenomenological evolution of blast damage of plates.

ABSTRACT: In this work, Donnell’s non-linear shallow shell equations are used to study the dynamic instability of imperfect simply supported orthotropic cylindrical shells with internal flowing fluid subjected to a compressive axial static pre-load plus a harmonic axial load. The fluid is assumed to be non-viscous and incompressible and the flow isentropic and irrotational. An expansion with eight degrees of freedom,
containing the fundamental, companion, gyroscopic and five axi-symmetric modes is used to describe the lateral displacement of the shell. The geometric imperfections are described by the same expansion as the lateral displacement and the Galerkin method is used to obtain the non-linear equations of motion which are, in turn, solved by the Runge-Kutta method. Numerical methods are used to identify the most important bifurcations as the fluid flow is varied, special attention is given to the influence of the material properties and the influence of initial geometric imperfection on the global stability of the system.

“Nonlinear vibrations of axially loaded cylindrical shells partially filled with fluid”
9th Brazilian Conference on Dynamics, Control and their Applications, June 7-11, 2010

ABSTRACT: This work investigates the nonlinear dynamic behavior and instabilities of partially fluid-filled cylindrical shell subjected to axial load. A discrete low-dimensional model for the nonlinear vibration analysis is derived to study the shell vibrations. The influence played by the height of the internal fluid on the nonlinear shell response is examined.

References listed at the end of the paper:

ABSTRACT: In the present study, the geometrically nonlinear vibrations of circular cylindrical shells, subjected to internal fluid flow and to a radial harmonic excitation in the spectral neighbourhood of one of the lowest frequency modes, are investigated for different flow velocities. The shell is modelled by Donnell's nonlinear shell theory, retaining in-plane inertia and geometric imperfections; the fluid is modelled as a potential flow with the addition of unsteady viscous terms obtained by using the time-averaged Navier–Stokes equations. A harmonic concentrated force is applied at mid-length of the shell, acting in the radial direction. The shell is considered to be immersed in an external confined quiescent liquid and to contain a fluid flow, in order to reproduce conditions in previous water-tunnel experiments. For the same reason, complex boundary conditions are applied at the shell ends simulating conditions intermediate between clamped and simply supported ends. Numerical results obtained by using pseudo-arclength continuation methods and bifurcation analysis show the nonlinear response at different flow velocities for (i) a fixed excitation amplitude and variable excitation frequency, and (ii) fixed excitation frequency by varying the excitation amplitude. Bifurcation diagrams of Poincaré maps obtained from direct time integration are presented, as well as the maximum Lyapunov exponent, in order to classify the system dynamics. In particular, periodic, quasi-periodic, subharmonic and chaotic responses have been detected. The full spectrum of the Lyapunov exponents and the Lyapunov dimension have been calculated for the chaotic response; they reveal the occurrence of large-dimension hyperchaos.

ABSTRACT:
Given the superior strength-to-weight ratio, stiffened panels have been used extensively in the main structure of ships and underwater vehicles. The loads acting on a stiffened panel in a ship is in-plane compression or tension, resulting from the overall hull-girder bending moment or torsion, shear force resulting from the hull-girder shear force, and lateral pressure resulting from the external wave or shock loading. This work addresses the transient responses of a panel structure reinforced by ribs of different sizes to underwater shock loads using non-linear finite element code-ABAQUS. Verification of the reliability was made between the Ramajeyathilagam’s experiments results [Ramajeyathilagam K, Vendhan CP, Rao VB. Non-linear transient dynamic response of rectangular plates under shock loading. Int J Impact Eng 2000;24:999–1015, Ramajeyathilagam K, Vendhan CP. Deformation and rupture of thin rectangular plates subjected to underwater shock. Int J Impact Eng 2004;30:699–719] at several different locations on the plates. The shock factor is adopted to describe the shock severity. Additionally, the displacement–time histories under different shock loadings are presented which will be used in designing stiffened panels so as to enhance resistance to underwater shock damage.

ABSTRACT: The transient response of submerged two-dimensional thin shell subjected to weak acoustical or mechanical excitations is addressed in this paper. The proposed approach is first exposed in a detailed manner: it is based on Laplace transform in time, in vacuo eigenvector expansion with time-dependent coefficients for the structural dynamics and boundary-integral formulation for the fluid. The projection of the fluid pressure on the in vacuo eigenvectors leads to a fully coupled system involving the modal time-dependent displacement coefficients, which are the problem unknowns. They are simply determined by matrix inversion in the Laplace domain. Application of the method to the response of a two-dimensional immersed shell to a weak acoustical excitation is then exposed: the proposed test-case corresponds to the design of immersed structures subjected to underwater explosions, which is of paramount importance in naval shipbuilding. Comparison of a numerical calculation based on the proposed approach with an analytical solution is exposed; versatility of the method is also highlighted by referring to “classical” FEM/FEM or FEM/BEM simulations. As a conspicuous feature of the method, calculation of the fluid response functions corresponding to a given geometry has to be performed once, allowing various simulations for different material properties of the structure, as well as for various excitations on the structure. This versatile approach can therefore be efficiently and extensively used for design purposes.

ABSTRACT: Explosion containment vessels (ECVs) are widely used to completely contain the effects of explosions. A theoretical model for calculating the dynamic plastic responses of discrete multi-layered explosion containment vessels (DMECVs) has been established, which considered the effects of the strain-hardening and strain-rate on the material. The maximum displacement and equivalent plastic strain formulae have been derived for “moving separately” and “moving together” response modes. With the considerations of the effects of strain-hardening and strain-rate, three-dimensional finite element models have been developed in LS-DYNA to calculate the dynamic plastic responses of DMECVs under partial loadings. It shows that analytical and numerical results support each other, which indicates their validity. The two response modes of DMECV are confirmed in different material combinations, and a non-membrane response phase of the outer ribbon layers has been identified. Furthermore, the equivalent plastic strain of the outer ribbon layer does not change during the non-membrane response phase, which is an important characteristic for the dynamics of DMECVs.

ABSTRACT: The objective of this combined numerical and experimental study is to analyze the dynamic response of sandwich structures which play an important role in applications requiring shock resistance, high capacity for energy-absorption and out-of-plane shear strength. This investigation focuses on the overall structural response, deformation, damage, and energy-absorption through delamination and core crushing. Air-backed and water-backed/submerged composite structures are subject to a range of blast loading. The damage and failure characteristics of individual components of the sandwich structures are studied using laser-based in-situ diagnostics and postmortem analysis. In the finite-element simulations, the underwater blast loading intensity is considered using the Mie-Gruneisen equation-of-state of a linear Hugoniot form. Configurations analyzed include polymer foam core structures with planar and cylindrical geometries. Core crushing is accounted for through the crushable foam plasticity model. Calculations reveal a significant difference between the response of air-backed and water-backed/submerged structures in terms of deflection, core crushing and energy-absorption. The experiments and computations offer approaches for improving the blast mitigation capabilities of submerged composite sandwich structures in the critical parts of a ship structure like keel, turbine-blades and rudders.

Netto (Ocean Engineering Department, Federal University of Rio de Janeiro, Brazil), “On the dynamic collapse of cylindrical shells under hydrostatic and impulsive pressure loadings”, Mecánica Computacional Vol XXIX, págs. 7787-7797, Eduardo Dvorkin, Marcela Goldschmit, Mario Storti (Eds.) Buenos Aires, Argentina, 15-18 Noviembre 2010

ABSTRACT: The dynamic collapse of submerged cylindrical shells subjected to lateral impulsive pressure loads caused by underwater explosions is studied via coupled experimental and numerical work. The parent problem of the dynamic collapse of such structures under hydrostatic pressure is also investigated. Two sets of experiments were performed. Initially, 50.6mm outside diameter aluminum tubes with diameter-to-thickness ratio of 32.3 were tested inside a pressure vessel. Hydrostatic pressure was applied quasi-statically up to the onset of collapse in order to obtain the collapse pressure of the tubes tested. Subsequently, similar tubes were tested in a 5m x 5m x 1.6m deep water tank under various explosive charges placed at different distances. Explosive charges and standoff distances were combined so as to eventually cause collapse of the specimens. In both sets of experiments, dynamic pressure and strain measurements were recorded using a fit-for-purpose data acquisition system with sampling rates of up to 1 Mega Samples/sec per channel. In parallel, finite element models were developed using commercially available software to simulate underwater explosion, pressure wave propagation, its interaction with a cylindrical shell and the subsequent onset of dynamic collapse. The surrounding fluid was modeled as an acoustic medium, the shells as J2 flow theory based materials with isotropic hardening, and proper fluid-structure interaction elements accounting for relatively small displacements of the boundary between fluid and structure were used. Finally, the physical explosion experiments were numerically reproduced with good correlation between results.

ABSTRACT: This study investigates the dynamic linear, nonlinear responses, and shock damage of two kinds of submerged cylindrical shell models exposed to underwater spherical trinitrotoluene (TNT) charge explosions in a circular lake. Two endplates and a middle plate are mounted on the cylindrical shells to provide support and create two enclosed spaces. The two kinds of cylindrical shell models are unfilled and main hull sand-filled, respectively. Fifteen different tests are carried out according to changing the TNT explosive weights of 1 kg and 2 kg, standoff distances ranging from 3 m to 0.3 m, and two explosion positions, and the measured experimental results are compared with each other. Detailed discussions on the experimental results show that the dynamic responses and damage modes are much different, and the main hull sand-filled cylindrical shell is more difficult to be damaged by the shock wave loading than the unfilled model. The edge cracks are mainly observed at the instrument hull of the main hull sand-filled model, but surface tearing and cracks take place both on the main and instrumental hulls of the unfilled model, respectively.

ABSTRACT: An approximation solution is introduced for the dynamic response of a two-layered cylindrical shell of circular cross-section subjected to an underwater explosive shock wave. The solution is obtained within the framework of the Flügge thin shell theory and the reflected-afterflow-virtual-source (RAVS) method is used to account for the fluid–structure interaction. Detailed numerical computations are carried out, in dimensionless form, for the cases of infinitely long two-layered cylindrical shells. Time histories of nondimensional radial velocity, mid-surface strain, 0th mode radial displacement and 1st mode radial velocity are presented in graphical form and the effects of elastic modulus, shell radius and thickness on the transient response characteristics of the shells are investigated.

ABSTRACT: (cannot cut and paste)

ABSTRACT: The security evaluation of some structures shocked by an underwater explosion (UNDEX) frequently plays a key role in some cases, and it is necessary to accurately predict the damage condition of the structure in an UNDEX environment. This study investigates the dynamic linear and non-linear responses and shock damages of two kinds of submerged cylindrical shell models exposed to underwater spherical trinitrotoluene (TNT) charge explosions in a circular lake. Two endplates and a middle plate are mounted on the cylindrical shells to provide support and to create two enclosed spaces. The two kinds of cylindrical shell models with the same geometry characteristics are unfilled and main hull sand-filled. Fifteen different tests are carried out by changing the TNT explosive weights of 1 and 2 kg, standoff distances ranging from 3 to 0.3 m, and two explosion positions. Measured experimental results are compared with each other, and some transformed data are obtained. A detailed discussion on experimental results shows that the dynamic responses and damage modes are much different, and the main hull sand-filled cylindrical shell is more difficult to be damaged by the shock wave loading than the unfilled model. Edge cracks are mainly observed at the instrument
hull of the main hull sand-filled model, but surface tearing and cracks are observed on both the main hull and the instrumental hull of the unfilled model, respectively.

H. Shah Mohammadi and S. Mohammadi (School of Civil Engineering, University of Tehran, Iran), “Analysis of blast shock waves on immersed pipes”, Civil Engineering Infrastructures Journal (CEIJ), Vol. 44, No. 1, pp 61-72, March 2010

ABSTRACT: As a result of wide spread application of marine structures, especially in oil and gas industries, their safe design is of paramount importance. In this regard, explosion loading, which may result from accidents or military/terrorist actions, should be considered, although they may not always be included in the final structural design. The impulsive nature of explosive loading, which comprises a high peak pressure followed by a relative fast decay, and complex phenomena of reflection of incident waves on flexible curved surfaces of a structure, leads to highly complicated analysis of underwater explosion. Detonation of a high explosive material under water produces two pressure pulses: a shock wave which has a very short duration (about several ten to several hundred micro seconds) and a bubble pulse associated with the expansion of the products of detonation. Roles of the underwater shock wave, flow and bubble in the damage process of structures are not as yet, clear. Only effects of the primary shock wave generated from an explosion on circular and rectangular plate specimens and empty submerged cylinders are studied in this research. Effects of bed and water surfaces are not taken into account. The structure and its surrounding water are modeled by solid finite elements. They are attached to each other to enforce for coupling analysis. The water is bounded by nonreflecting boundaries to avoid unwanted reflections from the finite boundaries of the domain. Results of the numerical simulations are compared to the experimental data and the results obtained from available empirical relations.

ABSTRACT: The underwater blast response of free standing sandwich plates with a square honeycomb core
and a corrugated core has been measured. The total momentum imparted to the sandwich plate and the degree of core compaction are measured as a function of (i) core strength, (ii) mass of the front face sheet (that is, the wet face) and (iii) time constant of the blast pulse. Finite element calculations are performed in order to analyse the phases of fluid-structure interaction. The choice of core topology has a strong influence upon the dynamic compressive strength and upon the degree of core compression, but has only a minor effect upon the total momentum imparted to the sandwich. For both topologies, a reduction in the mass of the front (wet) face reduces the imparted momentum, but at the expense of increased core compression. Conversely, an increase in the time constant of the blast pulse results in lower core compression, but the performance advantage over a monolithic plate in terms of imparted momentum is reduced. The sandwich panel results are compared with analytical results for monolithic plates of mass equal to that of (i) the sandwich panel and (ii) the front face alone. (Case (i) represents a rigid core while (ii) represents a core of negligible strength.) For most conditions considered, the sandwich results lie between these limits reflecting the coupled nature of core deformation and fluid-structure interaction.

ABSTRACT: This paper presents numerical simulations of dynamic responses of a ship section to non-contact underwater explosion using ABAQUS. The finite element model of the ship section including the size of fluid mesh, initial and boundary conditions etc. has been built up. Comparisons of the acceleration and velocity response between the experimental and numerical results have been investigated. The numerical results agree well with the measured results. Furthermore, the effect of the mass proportional damping factor on the velocity response have been investigated numerically. The dynamic response modes of the ship section subjected to a side-on non-contact underwater explosion are discussed.

ABSTRACT: Predicting the dynamic response of submerged vehicles subjected to hydrostatic pressure and underwater shock loading is of great interest to many structural designers and engineers for improving material and configuration design in recent years. In this paper, the finite element method is used to evaluate the dynamic response of a submerged cylindrical foam core sandwich panel subjected to shock loading. The sandwich panel consists of a foam core surrounded by fiber-reinforced laminates. The effect of fluid–structure coupling is included in the finite element analysis whereas the fluid is assumed to be compressible and inviscid. Time histories of circumferential stress for different composite plies are presented in graphical form and the effects of core type on circumferential stress and velocity of stand-off point are also investigated. Additionally, the distribution of pressure in fluid domain and the deformation of cylindrical foam core sandwich panel are estimated. To the best of the authors’ knowledge, the specialized literature addressing the dynamic response of submerged cylindrical foam core sandwich panel to underwater shock loading is rather scanty. This work is likely to fill a gap in the specialized literature on this topic.

ABSTRACT: An experimental investigation was conducted to evaluate the dynamic performance of E-glass Vinyl Ester composite face sheet / foam core sandwich panels when subjected to pre-compression and subsequent blast loading. The sandwich panels were subjected to 0 kN, 15 kN and 25 kN of in plane compression respectively, prior to transverse blast wave loading with peak incident pressure of 1 MPa and velocity of 3 Mach. The blast loading was generated using a shock tube facility. During the experiments, a high-speed photographic system utilizing three digital cameras was used to acquire the real-time 3-D deformation of the sandwich panels. The 3D Digital Image Correlation (DIC) technique was used to quantify the back face out-of-plane deflection and in-plane strain. The results showed that in-plane compressive loading facilitated buckling and failure in the front face sheet. This mechanism greatly reduced the blast resistance of sandwich composites.

LeBlanc, J., Shukla, A., 2011. Dynamic response of curved composite panels to underwater explosive loading: experimental and computational comparisons. Compos. Struct. Vol 93, No. 11, pp 3072–3081, October 2011 ABSTRACT: The response of E-Glass/Vinyl ester curved composite panels subjected to underwater explosive loading has been studied. The work consists of experimental testing utilizing a water filled conical shock tube facility and computational simulations with the commercially available LS-Dyna finite element code. The composite specimens are 0/90 biaxial laminates with a thickness of approximately 1.3 mm. The samples are round panels with curved midsections. The transient response of the plates is measured using a three-dimensional (3D) Digital Image Correlation (DIC) system, along with high speed photography. This ultra high speed system records full field shape and displacement profiles in real time. The DIC data and the computational results show a high level of correlation using the Russell error measure.

“Dynamic response of the non-contact underwater explosion on naval equipment”, Marine Struct., 24(4): 396–411, 2011 ABSTRACT: Shock resistance capacity of the shipboard equipment especially for large ones, has been a strong concern of navies all over the world for a long time. The shipboard equipment have previously generally been studied separate from hull structure before. In this paper the coupling elastic effect between equipment and hull structure is taken into account. With the ABAQUS software, the integrated model of the equipment coupled with the hull structure is established to study the dynamic response of the shipboard equipment to the shock wave load as well as the bubble pulsation load. In order to verify the numerical method, the simulated results are compared to the experimental data, which are from a specific underwater explosion on an actual ship. On this basis, by changing the charge location, attack angle, equipment installation location and other parameters, the characteristics of dynamic response under different conditions can be obtained. In addition, the results of the integrated calculation and the non-integrated one are compared and the characteristic parameters which affect the equipment shock response are analyzed. Some curves and conclusions are obtained for engineering applications, which provides some insights into the shock resistance of shipboard equipment.

ABSTRACT: Whipping response will happen when a ship is subjected to underwater explosion bubble load. In that condition, the hull would be broken, and even the survivability will be completely lost. A calculation method on the dynamic bending moment of bubble has been put forward in this paper to evaluate the impact of underwater explosion bubble load on the longitudinal strength of surface ships. Meanwhile the prediction equation of bubble dynamic bending moment has been concluded with the results of numerical simulation. With wave effect taken into consideration, the evaluation method of the total damage of a ship has been established. The precision of this evaluation method has been proved through the comparison with calculation results. In order to verify the validity of the calculation results, experimental data of real ship explosion is applied. Prediction equation and evaluation method proposed in this paper are to be used in ship structure design, especially in the preliminary prediction of the ultimate withstanding capability of underwater explosion damage for the integrated ship in preliminary design phase.

ABSTRACT: The aim of the present paper is to study the parametric instability and snap-through buckling of an axially pre-loaded, partially fluid-filled cylindrical shell. The Donnell non-linear shallow shell theory is used to study the nonlinear vibrations of the shell. For this, the Galerkin method is used, together with a suitable expansion that takes into account the main nonlinear interactions, to discretize the shell. The resulting nonlinear equations of motion are solved by numerical integration. The fluid is assumed to be non-viscous and incompressible and its inertial effects on the shell surface are obtained by the potential flow theory. A detailed parametric analysis is carried out to demonstrate the influence of the fluid height within the shell on the parametric instability load and on the snap-through buckling load in the main parametric resonance region. Using bifurcations diagrams, the main bifurcation events associated with these stability boundaries are identified. The influence of the different types of bifurcation and fluid height on the safety is also discussed. References listed at the end of the paper:

ABSTRACT: The nonlinear flutter oscillations of a traditional composite shallow shell subject to combined aerodynamic and thermal loads are investigated. A nonlinear finite element model is developed using Marguerre curved plate theory with von Karman geometric nonlinearity and the principle of virtual work. The aerodynamic pressure is modeled using the quasi-steady first-order piston theory. Thermal load is assumed to be steady state constant temperature distribution. Nonlinear temperature-dependence of material properties is considered in the formulation. The dynamic nonlinear equations of motion are transformed to modal coordinates to reduce the computational efforts. Newton-Raphson iteration method is employed to obtain the dynamic response at each time step of the Newmark numerical integration scheme. Finally, numerical results for the nonlinear flutter limit-cycle oscillations of composite shallow shells are presented, illustrating the effect of aerodynamic pressure and temperature rise on the panel response.

ABSTRACT: This paper review focuses mainly on development and application of a hybrid finite element approach used for linear and geometrically nonlinear vibration analysis of isotropic and anisotropic plates and shells, with and without fluid-structure interaction. Development of a hybrid element for different geometries of plates and shells is briefly discussed. In addition, studies dealing with particular dynamic problems such as dynamic stability and flutter of plates and shells coupled to flowing fluids are also discussed. This paper is structured as follows: after a short introduction on some of the fundamentals of the developed model applied to vibrations analysis of shells and plates in vacuo and in fluid, the dynamic analysis of anisotropic structural elements is discussed. Studies on dynamic response of plates in contact with dense fluid (submerged and/or subjected to liquid) follow. These studies present very interesting results that are suitable for various applications. Dynamic response of shell type structures subjected to random vibration due to a turbulent boundary layer of flowing fluid is reviewed. Aeroelasticity analysis of shells and plates (including the problem of stability; divergence and flutter) in contact with light fluids (gases) are also discussed. ABSTRACT: Underwater contact explosion involves lots of complex issues such as high speed, strong compression, large deformation and density ratio, multi-phase flow, etc., which makes the numerical simulation extremely difficult. In this paper, a modified SPH approach based on volume approximation is applied and the entire process of shock wave propagation and structure destruction is successfully simulated. Results show that the modified method remains effective at interfaces with high density ratio, with no distortion of physical quantities. Therefore, the method has advantages of solving problems involving high speed, strong compression and high density ratio. In addition, shock wave propagation characteristics and a steel failure mod are found with simulation, which can be valuable reference for structural design of naval architecture and engineering of underwater explosion.

ABSTRACT: The propagation of the shock wave and the bubble pulse of an underwater explosion and the dynamic response of a cylindrical shell were examined in a water pool. Numerical simulations of the experimental model were performed using the MSC.DYTRAN software, which included a developed subroutine that defined the initial conditions of the fluid field. A fluid-structure interaction method was introduced to define the interaction between the water and the cylindrical shell. The finite element models were built according to the experimental models, and the calculated results were compared with the experimental data. It was found that the artificial bulk viscosity had a significant effect on the peak pressure of the shock wave. The peak pressure of the shock wave, the period of the bubble pulse and the deformation displacement of the cylinder were consistent between the experiment and the finite element analysis. The effects of the length-to-diameter ratio and the angle to the peak pressure of the shock wave for a cylindrical explosive were discussed. Different plastic deformations were measured at different standoff distances, obtaining generalising curves.

ABSTRACT: Laboratory-scale fluid-structure interaction (FSI) experiments are performed in order to examine the response of submerged, clamped composite plates to dynamic loading by underwater shock waves. Experiments are conducted in a recently developed transparent shock tube [1] and allow measurements of deflection history and cavitation processes. Analytical models are implemented for the underwater blast response of orthotropic composite plates and analytical predictions are compared to those of explicit finite element (FE) simulations and to experimental evidence.

Gong, Shi Wei and Lam, Khin Yong (SingaporeNanyang Technological University, Singapore), “Functionally graded shells subjected to underwater shock”, American Institute of Physics Conference, 2012, DOI: 10.1063/1.3686251

ABSTRACT: This paper deals with the problem of functionally graded (FG) cylindrical shells subjected to underwater shock. A computational approach to predict the dynamic response of the FG cylindrical shells to underwater shock is presented. The effective material properties of functionally graded materials (FGMs) for the cylindrical shells are assumed to vary continuously through the shell thickness and are graded in the shell thickness direction according to a volume fraction power law distribution. Based on Doubly Asymptotic Approximation (DAA) method, the fluid-structure interaction equation for a submerged structure is derived, in which the constitutive relation for functional graded material is implemented. The coupled fluid-structure equations, relating structure response to fluid impulsive loading, are solved using coupled finite-element and
boundary-element codes. The computational procedure for the prediction of transient response of the FG graded cylindrical shells subjected to underwater shock is described, with a discussion of the results.

"Parallel computing of the underwater explosion cavitation effects on full-scale ship structures”, Journal of Marine Science and Application, Vol. 11, No. 4, pp 469–477, December 2012

ABSTRACT: As well as shock wave and bubble pulse loading, cavitation also has very significant influences on the dynamic response of surface ships and other near-surface marine structures to underwater explosive loadings. In this paper, the acoustic-structure coupling method embedded in ABAQUS is adopted to do numerical analysis of underwater explosion considering cavitation. Both the shape of bulk cavitation region and local cavitation region are obtained, and they are in good agreement with analytical results. The duration of reloading is several times longer than that of a shock wave. In the end, both the single computation and parallel computation of the cavitation effect on the dynamic responses of a full-scale ship are presented, which proved that reloading caused by cavitation is non-ignorable. All these results are helpful in understanding underwater explosion cavitation effects.

ABSTRACT: The focus of the paper is on the numerical analysis of cylinder shells with arbitrary cross-section, containing flowing fluid. A three-dimensional problem is considered and solved by the finite element method. The motion of the shell is described by applying the variational principle of virtual displacements, which incorporates the linearized Bernoulli equation for evaluating the hydrodynamic pressure. A compressible inviscid fluid is considered.

Strengthening the framework of the potential theory. The governing equations are converted using the Bubnov–Galerkin method. To demonstrate the possibilities of three-dimensional numerical simulation two problems on the natural vibrations and stability of elliptical cylindrical shells are investigated.

ABSTRACT: In the present work, a set of finite element analyses (FEA) was carried out, using Abaqus to reproduce the mechanical behaviour of integrally stiffened panels when subject to longitudinal compression. Since most fabrication processes, such as welding, introduce distortions and affect the material properties, the sensitivity to these defects was assessed. Different shapes and magnitudes of the initial geometrical imperfections were tested and a high sensitivity was observed to both factors on the ultimate load. The existence of a heat affected material showed no influence on the ultimate strength of the tested panels.

ABSTRACT: Protection of structures against explosions due to terrorism actions or accidents is a growing concern in the current times. The need for engineers to understand the structural mechanics during blast load events motivated the research leading to this work. This paper investigates the structural response of integrally stiffened panels, with different stiffener configurations, subjected to blast loading conditions through a set of finite element analyses (FEA) carried out using LS-Dyna commercial code. The numerical models developed in this work are validated by comparing the results to two small-scale blast loading experiments presented in the literature. The influence of different parameters, such as, numerical (i.e. element type, element size) and geometrical parameters, with respect to the accuracy of the finite element results are investigated. It is concluded which numerical parameters present the more accurate results with reduced computational effort and which stiffener configuration results in a more stable behaviour for the structure.

ABSTRACT: When a naval ship is attacked by an underwater explosion (UNDEX), the ship can be severely damaged by shock waves and gas bubble pulse: such an attack can put the crew in danger and possibly destroy the ship. Preventing damage to ships is of great interest in ship design. Elastomers, or rubber-like materials, and core sandwich structure are well known to reduce impact loading. This study researched these materials, structures and verified their ability to mitigate shock loading in an UNDEX environment. Furthermore, formulas to optimize sandwich structure design are presented and its effectiveness has been confirmed.

ABSTRACT: A submerged evacuated circular cylindrical shell subjected to a sequence of two external shock waves generated at the same source is considered. A semi-analytical model combining the classical methods of mathematical physics with the finite-difference methodology is developed and employed to simulate the interaction. Both the hydrodynamic and structural aspects of the problem are considered, and it is demonstrated that varying the delay between the first and second wavefronts has a very significant effect on the stress–strain state of the structure. In particular, it is shown that for certain values of the delay, the constructive superposition of the elastic waves travelling around the shell results in a ‘resonance-like’ increase of the structural stress in certain regions. The respective stress can be so high that it sometimes exceeds the overall maximum stress observed in the same structure but subjected to a single-front shock wave with the same parameters, in some cases by as much as 50%. A detailed parametric analysis of the observed phenomenon is carried out, and an easy-to-use diagram summarizing the finding is proposed to aim the pre-design analysis of engineering structures.

ABSTRACT: The development of efficient algorithms to understand implosion dynamics presents a number of challenges. The foremost challenge is to efficiently represent the coupled compressible fluid dynamics of internal air and surrounding water. Secondly, the method must allow one to accurately detect or follow the interface between the phases. Finally, it must be capable of resolving any shock waves which may be created in air or water during the final stage of the collapse. We present a fully Lagrangian compressible numerical framework for the simulation of underwater implosion. Both air and water are considered compressible and the equations for the Lagrangian shock hydrodynamics are stabilized via a variationally consistent multiscale method. A nodally perfect matched definition of the interface is used and then the kinetic variables, pressure and density, are duplicated at the interface level. An adaptive mesh generation procedure, which respects the interface connectivities, is applied to provide enough refinement at the interface level. This framework is then used to simulate the underwater implosion of a large cylindrical bubble, with a size in the order of cm. Rapid collapse and growth of the bubble occurred on very small spatial (0.3mm), and time (0.1ms) scales followed by Rayleigh-Taylor instabilities at the interface, in addition to the shock waves traveling in the fluid domains are
ABSTRACT: In this paper, a scaled 3D ship under shock loading is modeled and analyzed by finite element method. By using a shock factor, there is no need to have different tests or even numerical simulation. Shock factor is an important parameter which clarifies shock severity. It was found that although the new shock factor introduced by Yao et al. (2009), when constant, predict the response better than older shock factor, but for varying values of shock factors, the older would predict better. It is also found that costly and time-consuming experiments can be avoided by proper finite element modeling, yet the errors can remain within an acceptable range. The results of the present work can be used as benchmarks for future works.

ABSTRACT: Nonlinear free vibration and instability of fluid-conveying double-walled boron nitride nanotubes (DWBNNTs) embedded in viscoelastic medium are studied in this paper. The effects of the transverse shear deformation and rotary inertia are considered by utilizing the Timoshenko beam theory. The size effect is applied by the modified couple stress theory and considering a material length scale parameter for beam model. The nonlinear effect is considered by the Von Kármán type geometric nonlinearity. The electromechanical coupling and charge equation are employed to consider the piezoelectric effect. The surrounding viscoelastic medium is described as the linear visco-Pasternak foundation model characterized by the spring and damper. Hamilton’s principle is used to derive the governing equations and boundary conditions. The differential quadrature method (DQM) is employed to discretize the nonlinear higher-order governing equations, which are then solved by a direct iterative method to obtain the nonlinear vibration frequency and critical fluid velocity of fluid-conveying DWBNNTs with clamped-clamped (C-C) boundary conditions. A detailed parametric study is conducted to elucidate the influences of the small scale coefficient, spring and damping constants of surrounding viscoelastic medium and fluid velocity on the nonlinear free vibration, instability and electric potential distribution of DWBNNTs. This study might be useful for the design and smart control of nano devices.

We experimentally and numerically investigate the response of fluid-filled composite tubes under shock wave loading. Our study focuses on the fluid–structure interaction when the shock wave in the fluid propagates parallel to the axis of the tube, creating pressure waves in the fluid coupled to flexural waves in the shell. The in-house-developed computational scheme couples an Eulerian fluid solver with a Lagrangian shell solver, which includes a new and simple material model to capture the response of fiber composites in finite kinematics. In the experiments and simulations we examine tubes with fiber winding angles equal to 45° and 60°, and we measure the precursor and primary wave speeds, hoop and longitudinal strains, and pressure. The experimental and computational results are in agreement, showing the validity of the computational scheme in complex fluid–structure interaction problems involving fiber composite materials subjected to shock waves. The analyses of the measured quantities show the strong coupling of axial and hoop deformations and the significant effect of fiber winding angle on the composite tube response, which differs substantially from that of a metal tube in the same configuration.

ABSTRACT: In the present study, a hybrid finite element method is applied to investigate the dynamic behavior of a spherical shell partially filled with fluid and subjected to external supersonic airflow. The structural formulation is a combination of linear spherical shell theory and the classic finite element method. In this hybrid method, the nodal displacements are derived from exact solution of spherical shell theory rather than approximated by polynomial functions. Therefore, the number of elements is a function of the complexity of the structure and it is not necessary to take a large number of elements to get rapid convergence. Linearized first-order potential (piston) theory with the curvature correction term is coupled with the structural model to account for aerodynamic loading. It is assumed that the fluid is incompressible and has no free surface effect. Fluid–structure and fluid–structure–bubble interaction effects during underwater explosions near composite structures. ABSTRACT: In this paper, the entity model of a 1.5 MW offshore wind turbine blade was built by Pro/Engineer software. Fluid flow control equations described by arbitrary Lagrange-Euler (ALE) were established, and the theoretical model of geometrically nonlinear vibration characteristics under fluid-structure interaction (FSI) was given. The simulation of offshore turbulent wind speed was achieved by programming in Matlab. The brandish displacement, the Mises stress distribution and nonlinear dynamic response curves were obtained. Furthermore, the influence of turbulence and FSI on blade dynamic characteristics was studied. The results show that the response curves of maximum brandish displacement and maximum Mises stress present the attenuation trends. The region of the maximum displacement and maximum stress and their variations at different blade positions are revealed. It was shown that the contribution of turbulence effect (TE) on displacement and stress is smaller than that of the FSI effect, and its extent of contribution is related to the relative span length. In addition, it was concluded that the simulation considering bidirectional FSI (BFSI) can reflect the vibration characteristics of wind turbine blades more accurately.

ABSTRACT: The response of single-curvature composite panels under external blast was studied. For the single-curvature composite shells under external pressure pulse loading, Lagrange’s equations of motion were established to determine the shell response and the Budiansky-Roth criterion was used to examine the instability. The predicted transient shell response compared very well with FEA results from ABAQUS Implicit, and the predicted buckling loads also agreed with experiments on steel arches. Under various load durations, buckling was impulsive, dynamic and quasi-dynamic. Thicker composite shells were more likely to fail by first-ply failure rather than buckling. It was shown that the composite lay-up could be adjusted to increase the buckling resistance of the shell. For the single-curvature composite sandwich panels under external pressure pulse loading, a multi-layered approach was used to distinguish facesheets and core deformations. Core compressibility and transverse shear through the thickness were accounted for using linear displacement fields through the thickness. Equations of motion for the facesheet transient deformations were again derived from Lagrange’s equations of motion, and predicted solutions using this approach compared very well with FEA results from ABAQUS Implicit. In the case of core undergoing elastic deformations only, both facesheet fracture during stable deformation response and local dynamic pulse buckling of facesheets were considered as possible modes of failure in the curved sandwich panel. It was found that local facesheets buckling is more likely to occur than facesheet fracture in thin and deeply curved sandwich panels. The facesheet laminate lay-up could also be adjusted to improve the local buckling resistance of the curved sandwich panel. In the case of the core undergoing elastic-plastic deformations, a parametric study showed that blast resistance of the curved sandwich panel can be increased by allowing cores to undergo plastic crushing. Very thick (i.e., radius-to-thickness aspect ratio less than 10) and shallow shells derived much of their resistance to blast from core crushing. Strong, dense foam cores did not increase the blast resistance of the curved sandwich panel but allowed facesheets to fracture while the core remained elastic.

ABSTRACT: The problem of the stability of a fluid-conveying pipeline modeled by a composite orthotropic cylindrical shell of finite length with different boundary conditions at the ends is solved. The shell is subject to hydrodynamic pressure and uniform external static load. The effect of boundary conditions of the shell under external loading on the qualitatively different types of instability, quasistatic (divergence) and dynamic (flutter), that occur at certain “critical” velocities of the fluid is studied.

ABSTRACT: In this study, the vibration and stability analysis of a single-walled carbon nanotube (SWCNT) conveying nanoflow embedded in biological soft tissue are performed. The effects of nano-size of both fluid flow and nanotube are considered, simultaneously. Nonlocal beam model is used to investigate flow-induced vibration of the SWCNT while the small-size effects on the flow field are formulated through a Knudsen number (Kn), as a discriminant parameter. Pursuant to the viscoelastic behavior of biological soft tissues, the SWCNT is assumed to be embedded in a Kelvin–Voigt foundation. Hamilton's principle is applied to the energy expressions to obtain the higher-order governing differential equations of motion and the corresponding higher-order boundary conditions. The differential transformation method (DTM) is employed to solve the differential equations of motion. The effects of main parameters including Kn, nonlocal parameter and mechanical behaviors of the surrounding biological medium on the vibrational properties of the SWCNT are examined.

ABSTRACT: Dynamic buckling of submerged structures is a challenging problem for which experimental data is scarce and generalized theoretical models are difficult to employ. In addition to the complexities of dynamic buckling, this problem features additional difficulties due to the strong fluid–solid interaction that is characteristic of structures submerged in a dense fluid. This chapter reviews some recent experiments in which time-resolved measurements of pressure and strain were made during the buckling of submerged tubes. This data clarifies the buckling behavior over a useful range of conditions and provides a means to validate theoretical models with a rigor not possible using post-collapse measurements alone. Observations from the experiments are then used to develop simple models of buckling and fluid–structure interaction; comparisons with the experimental data demonstrate good agreement in spite of the many simplifications used in the modeling.

ABSTRACT: Truncated Conical vessels are commonly used as liquid containers in elevated tanks. Despite the widespread of this type of structures worldwide, no direct code provisions are currently available covering their seismic analysis and design. During a seismic excitation, two components of hydrodynamic pressure develop inside a liquid-filled tank. Those are the impulsive component, which synchronizes with the vibration of the walls of the tank and the convective component associated with the free surface sloshing motion. The current study describes the seismic behaviour of an elevated conical tank having a composite steel/concrete construction. The study is conducted numerically using a coupled finite/boundary element model developed in-house. The walls of the tank are modeled using a degenerated consistent shell element. The impulsive component of the hydrodynamic pressure is formulated taking into account the fluid-structure interaction that occurs between the fluid pressure and the shell vibration. The numerical model also predicts the sloshing motion associated with a seismic excitation. Due to the inclination of the walls, the vertical component of seismic ground motion produces meridional axial stresses in a conical tank. As such, both the horizontal and vertical components of the seismic motion are considered in the study. Time history seismic analyses are conducted under a number of pre-recorded seismic excitations. The bending and membrane stresses obtained from the analyses are evaluated in various location of the structure and are compared to the values associated with hydrostatic pressure in order to assess the importance of seismic stresses in this type of structures. The maximum values for the free surface sloshing motion are also obtained from the seismic analyses. Finally, comparisons are made between the seismic forces calculated using the equivalent cylinder approach adopted in some of the design codes.

ABSTRACT: This paper presents investigation of combined mechanisms of collapse of discrete single-layer domes. Main factors influencing sustainable behavior are: morphology of the grid configuration, geometry and material characteristics of the structural elements, type of joints and the supporting conditions. On this basis, representative configuration of discrete spherical dome for structural analysis is selected. The numerical solution is performed by software based on the Finite Element Method. Several load cases are considered. These are consistent with the surfaces of influence that have been determined. In order to define the critical value of the load parameter, the loading is increased incrementally and iterative procedure is used in a given load step in order to exclude the structural elements which have reached their limit capacity. Thus the boundary equilibrium of the system is defined. The study reveals geometric nonlinearities by accounting for P-A effects, i.e. the influence of normal forces on the stiffness of the system. It is assumed that the displacements increase after exclusion of the elements which have reached their limit capacity. The equilibrium conditions are defined for the deformed shape of the structure. Results are presented in graphical and tabular form.

Here we consider the effect of underwater blasts on marine structures. Near the explosive charge, the explosion bubble can induce whipping of nearby structures and induce severe damage. Shock waves can propagate over long distances and cause damage to structural panels but usually do not transfer enough momentum to induce overall deformation of the ship. Explosion bubbles oscillate with very low frequencies and can induce whipping of nearby structures and induce severe damage. In this work a geometric theory of diffraction is used to study the interaction of an underwater shock wave with fluid filled shells. The fluid inside may be different than the fluid outside the shell.

ABSTRACT: The influence of the outer hull on the response of a double hull structure induced by underwater explosion is studied. The simple plane wave theory was introduced to analyze the transmitting shock wave and the response of the structure. The calculation of transmission wave of the double cylindrical shell was carried on. The results show that the calculation of transmission wave is in quite agreement with the test data. The transmitting wave rate and transmitting wave energy decay in exponential curve with the thickness of the outer hull. The impulse contrast was increased a little. The peak value of transmitting wave was descended by 66.7%. Thickness of the outer hull is an extremely important factor to anti-shock capability of double cylindrical shell.

SUMMARY: In this work a geometrical theory of diffraction is used to study the interaction of an underwater shock wave with fluid filled shells. The fluid inside may be different than the fluid outside the shell. The shock waves can propagate over long distances and cause damage to structural panels but generally do not transfer enough momentum to induce overall deformation of the ship. Explosion bubbles oscillate with very low frequencies and can induce whipping of nearby structures and induce severe damage. Here we consider the effect of underwater blasts on nearby structures. Near the explosive charge, the
ABSTRACT: This paper presents a general approach for analysing the response of beam, plates and shells to short duration pressure pulses typically encountered as a result of underwater explosions. The problem is formulated in terms of curvilinear coordinates and the resulting equations can then be specialized for each particular geometry. Results are presented for several examples.

ABSTRACT: This chapter examines the interaction of shock waves generated by underwater explosions and submerged structures. Cylindrical shells filled with air, water, or a liquid with a different speed of sound are considered and the specific issue considered is the prediction of the position of the various wave fronts as a function of time. This is a challenging problem for both analytical and numerical approaches due to the sharp discontinuities, the complex shapes of these wave fronts and their numbers. A simple ray tracing procedure is developed to predict the exact position of all the wave fronts. It provides great insight into the physics of the problem and explains the evolution of the shape of the various fronts and the formation of singularities. Applications to the medical field are also presented.

In summary, the Rayleigh wave velocity can be expressed in terms of the elastic properties of the medium. Further research is needed to refine these expressions and to develop more accurate models for practical applications. The integrals over the mass density function can be challenging to compute, and numerical methods are often employed. Additionally, the simplified models are useful for preliminary assessments and for understanding the underlying physics of the problem.

The effects of high-rate impact and shock loading of structures have become an increasingly important design concern for various applications, particularly those of civil and military backgrounds. The mechanical properties, in particular high specific strength, of continuous Fibre Reinforced Polymer Composites (FRPCs) have been subject to widespread investigation. This is due to the increasing need for engineers to understand their performance and constraints with regard to the design of critical components. Moreover, FRPCs have been employed for naval ship superstructures owing to their low radar return. It would therefore be favourable to protect the integrity of the structure to prevent losses in stealth properties. This study outlines the recent high-rate impact studies conducted: high-speed photography, in conjunction with Digital Image
Correlation (DIC), has been used to monitor the deformation of sandwich FRPCs under shock loading of an air-blast to observe the failure mechanisms occurring during the event. Underwater-blast loading experiments were also conducted using strain gauges to monitor the response of the sandwich panel to the underwater shocks. Origins and mechanisms of failure such as core crushing, skin/core cracking and fibre breakage have been identified; moreover, the data reported provided further understanding of each loading case.

ABSTRACT: The resistance of glass-fibre reinforced polymer (GFRP) sandwich panels and laminate tubes to blast in air and underwater environments has been studied. Procedures for monitoring the structural response of such materials during blast events have been devised. High-speed photography was employed during the air-blast loading of GFRP sandwich panels, in conjunction with digital image correlation (DIC), to monitor the deformation of these structures under shock loading. Failure mechanisms have been revealed by using DIC and confirmed in post-test sectioning. Strain gauges were used to monitor the structural response of similar sandwich materials and GFRP tubular laminates during underwater shocks. The effect of the backing medium (air or water) of the target facing the shock has been identified during these studies. Mechanisms of failure have been established such as core crushing, skin/core cracking, delamination and fibre breakage. Strain gauge data supported the mechanisms for such damage. These studies were part of a research programme sponsored by the Office of Naval Research (ONR) investigating blast loading of composite naval structures. The full-scale experimental results presented here will aid and assist in the development of analytical and computational models. Furthermore, it highlights the importance of support and boundary conditions with regards to blast resistant design.

ABSTRACT: The study of underwater explosions (UNDEX) on ship/submarines became of interest during World War II when torpedo explosions near a ship created more damage than a direct hit. Following the war, many full scale ship shock trials were conducted by various countries providing the empirical data that is widely employed. The biggest threat to any marine platform is due to underwater weapons and hence understanding the phenomenon is essential. The sequence of events involved in an UNDEX starting from the detonation, shock wave, bubble pulses and cavitation have been introduced and the dynamics of the process including governing laws have been enumerated in the paper. The associated aspects of loading and method of analyzing the fluid structure interaction have also been highlighted. The development of such numerical methods to analyze the explosion and its effect on the fluid-structure can lead to design of safer ships and submarines. Moreover, the numerical simulation will eliminate the need for conducting expensive shock tests and trials.

Ikeda, C.M. and Duncan, J.H., “Explosion-induced implosions of cylindrical shell structures”, American Physical Society, 63rd Annual Meeting of the APS Division of Fluid Dynamics, November 2010

ABSTRACT: An experimental study of the explosion-induced implosion of cylindrical shell structures in a high-pressure water environment was performed. The shell structures are filled with air at atmospheric pressure and are placed in a large water-filled pressure vessel. The vessel is then pressurized to various levels $P = \alpha P_c$, where $P_c$ is the natural implosion pressure of the model and $\alpha$ is a factor that ranges from 0.1 to 0.9. An explosive is then set off at various standoff distances, $d$, from the model center line, where $d$ varies from $R$ to $10R$ and $R$ is the maximum radius of the explosion bubble. High-speed photography (27,000 fps) was used to observe the explosion and resulting shell structure implosion. High-frequency underwater blast sensors recorded dynamic pressure waves at 6 positions. The cylindrical models were made from aluminum (diameter $D = 39.1$ mm, wall thickness $t = 0.89$ mm, length $L = 240$ mm) and brass ($D = 16.7$ mm, $t = 0.36$ mm, $L = 152$ mm) tubes. The pressure records are interpreted in light of the high-speed movies. It is found that the implosion is induced by two mechanisms: the shockwave generated by the explosion and the jet formed during the explosion-bubble collapse. Whether an implosion is caused by the shockwave or the jet depends on the maximum bubble diameter and the standoff distance.
Christine M. Ikeda (Department of Mechanical Engineering, University of Maryland, College Park, Maryland, USA), “Fluid structure interactions: implosions of shell structures and wave impact on a flat plate”, Ph.D. dissertation, 2012, 3543523

ABSTRACT: The work in this dissertation examines the fluid-structure interaction phenomena in a series of three experimental studies. The first two sets of experiments were conducted in a large, water-filled pressure vessel with a nominal internal diameter of 1.77 m. Cylindrical shells were made from thin-walled aluminum and brass tubes with circular cross-sections (internal diameters D) and internal clearance-fit aluminum end caps. Implosion and explosion events were photographed with a high-speed camera (27,000 frames per second), and the waterborne pressure waves resulting from the implosion were measured simultaneously with underwater blast sensors. The natural implosions were generated by raising the ambient water pressure slowly to a value, P, just above the elastic instability limit of the models. For the models with larger L/D, where L is the internal length of the model, the model cross sections flattened during the implosion (mode 2). It was found that the amplitude of these mode 2 pressure waves scale with the pressure difference \( \Delta P = P - P_i \) (where \( P \) is the internal pressure of the air inside the cylindrical models) and the time scales with \( (D/2) \) [special characters omitted] (where \( \varphi \) is the density of water). The geometry and material properties of the structure seem to play only a secondary role. During the explosion experiments, the pressure vessel is pressurized to various pressure levels below the natural implosion pressure of the models and an explosive was set off nearby. It was found that the implosion is induced by one of two mechanisms: the shockwave generated by the explosion and the hydrodynamic pressure field of the explosion bubble during its collapse and re-expansion. In the final experimental study, the impact of a plunging breaking wave (wavelength \( \approx 1.2 \) m) on a partially submerged cube (with dimensions \( L = 0.3048 \) m) is studied in a wave tank (14.8 m long). The water free surface shape upstream of the cube before and after the wave impact was measured with a high-speed digital movie camera, and the pressure waves resulting from the implosion were measured simultaneously with underwater blast sensors. It was observed that for some cube positions, the free surface between the front face of the cube and the wave crest forms a circular arc that converges to a point and forms a high-velocity vertical jet (\( \approx 3 \) m/s). Although these problems are intrinsically different, they are flows dominated by inertial forces (viscous effects are not important) where a rapidly collapsing interface shape produces high-pressure waves.

ABSTRACT: The implosion of cylindrical shell structures in a high-pressure water environment is studied experimentally. The shell structures are made from thin-walled aluminium and brass tubes with circular cross sections and internal clearance-fit aluminium end caps. The structures are filled with air at atmospheric pressure. The implosions are created in a high-pressure tank with a nominal internal diameter of 1.77 m by raising the ambient water pressure slowly to a value, \( P \), just above the elastic stability limit of each shell structure. The implosion events are photographed with a high-speed digital movie camera, and the pressure waves are measured simultaneously with an array of underwater blast sensors. For the models with larger values of length-to-diameter ratio, \( L/D \), the tubes flatten during implosion with a two-lobe (mode 2) cross-sectional shape. In these cases, it is found that the pressure wave records scale primarily with \( P \) and the time scale \( R_i \sqrt{\rho_i/P_c} \) (where \( R_i \) is the internal radius of the tube and \( \varphi \) is the density of water), whereas the details of the structural design produce only secondary effects. In cases with smaller values of \( L/D \), the models implode with higher-mode cross-sectional shapes. Pressure signals are compared for various mode-number implosions of models with the same available energy, \( PV \), where \( V \) is the internal air-filled volume of the model. It is found that the pressure records scale well temporally with the time scale \( R_i \sqrt{\rho_i/P_c} \), but that the shape and amplitudes of the pressure records are strongly affected by the mode number.

ABSTRACT: An annular geometry is used to experimentally study fluid-structure interaction and dynamic buckling of tubes submerged in water and subjected to axially-propagating pressure waves. Wave propagation, vibration, and buckling of the specimen tubes are characterized using pressure and strain measurements. Emphasis is placed on pressures near or slightly exceeding the buckling threshold, where buckling deformation is excited but remains elastic or only slightly plastic due to the short duration of the pressure pulse. Measured wave speeds and non-axisymmetric vibration frequencies are in good agreement with predictions from simple fluid-structure interaction models. Near the buckling threshold, the amplitude of non-axisymmetric deformation is observed to grow rapidly with small increases in pressure until plastic deformation occurs, which results in a substantial loss of strength of the tube. Systematic mode 2 variations in wall thickness are found to control the buckle orientation, since the major axis of mode 2 buckles is always aligned with the location where the tube wall is thinnest.

ABSTRACT: In the underwater-shock environment, cavitation occurs near the structural surface. The dynamic response of fluid-structure interactions is influenced seriously by the cavitation effects. It is also the difficulty in the field of underwater explosion. With the traditional boundary element method and the finite element method (FEM), it is difficult to solve the nonlinear problem with cavitation effects subjected to the underwater explosion. To solve this problem, under the consideration of the cavitation effects and fluid compressibility, with fluid viscosity being neglected, a 3D numerical model of transient nonlinear fluid-structure interaction subjected to the underwater explosion is built. The fluid spectral element method (SEM) and the FEM are adopted to solve this model. After comparison with the FEM, it is shown that the SEM is more precise than the FEM, and the SEM results are in good coincidence with benchmark results and experiment results. Based on this, combined with ABAQUS, the transient fluid-structure interaction mechanism of the 3D submerged spherical shell and ship stiffened plates subjected to the underwater explosion is discussed, and the cavitation region and its influence on the structural dynamic responses are presented. The paper aims at providing references for relevant research on transient fluid-structure interaction of ship structures subjected to the underwater explosion.

ABSTRACT: Laboratory-scale fluid–structure interaction (FSI) experiments and finite element (FE) simulations are performed to examine the one-dimensional blast response of double-walled hulls, consisting of two skins sandwiching a layer of water. Both monolithic and sandwich designs are considered for the outer skin. Experiments are conducted in a transparent shock tube which allows measurements of water cavitation and hull response by high-speed photography. Experiments and FE predictions are found in good agreement and allow concluding that the impulse imparted to double hulls by underwater explosions can be dramatically reduced by employing the sandwich construction of the outer skin; such reductions are scarcely sensitive to the thickness of the water layer.

ABSTRACT: Bubble load in a noncontact underwater explosion can cause the ship hull global response and local response. In current literature, the ship hull is usually simplified as a hull girder to analyze its global response. However, literature dealt with the local response of a 3-D surface ship hull subjected to an underwater bubble were limited. This investigation develops a procedure which couples the finite element method with doubly asymptotic approximation (DAA) method to study the problem of transient responses of a ship hull structure subjected to an underwater explosion bubble. Using a 3-D ship model as examples, the global and local responses of the ship model in vertical, transverse and longitudinal directions are performed in detail. The acceleration, velocity and displacement time histories are presented. The characteristics of both the global and local responses of the ship model are discussed. The numerical results show that besides global whipping response, the ship hull also sustains severe local responses in different directions subjected to underwater explosion bubble jetting, which should be taken into consideration.

Oñate, J. Oliver and A. Huerta (Eds), Barcelona, Spain, 2014

ABSTRACT/PARTIAL INTRODUCTION: Fuselage panels in aircraft applications are reinforced structural parts subjected to strong buckling effects under normal flight loads. These loads are typically in-plane compression and in-plane shear solicitations, leading to complex buckling behaviors [1]. The ability of a structure to survive non-typical loads, i.e. blast loading from a terrorist attack or an incidental explosion, has also became a major concern. The detonation of an explosive material in the air generates an expanding shock front of finite amplitude moving supersonically [2]. The space and conditions between the point of detonation and the encountered obstacles affect the propagation and magnitude of the pressure wave, resulting in a complex transient structural load [3, 4, 5]. Advanced numerical techniques, such as the Finite Element Method (FEM), can be used in understanding the influence of the blast load and the resulting dynamic structural
response in detail. However, the reliability and stability of finite element results must be validated with experimental data. Analysis of the dynamic response of plates subjected to different kinds of impulsive loads has been an area of active research over the last decade [6, 7]. More recently, Spranghers et al. [2] presented an experimental and numerical study of aluminum plates under blast loading with some numerical considerations that are adopted in the present work. Also, Kumar et al. [8] presented a study on the response of aluminum plates under blast loading and the effect of the plates curvature on the structural response. Nurick et al. [9] presented an experimental study on the deformation and tearing of blast-loaded stiffened square steel plates. In addition, Nurick and Shave [10] and Teeling-Smith [11] performed experiments on plates attached to a ballistic pendulum under impulsive loads and presented an experimental study on the deformation and tearing of thin circular plates subjected to blast loading, respectively. Neuberger et al. [12, 13] measure the deflection of the central point of a circular plate subjected to free air blast loading and detonations of buried charges, obtaining a good agreement between numerical simulations predictions and test results. Finally, Ramajeyathilagam et al. [14] and Chan-Yung Jen et al. [15] both presented studies of the dynamic behaviour of rectangular plates and stiffened panels, respectively, subjected to underwater shock loading. In this study, the Finite Element Method was used to analyze the structural response of integrally stiffened panels (ISP) subject to a blast loading from a Composition C4 explosive material. For this purpose, two approaches were made in the development of the numerical models, the first approach corresponding to the validation of the numerical model. In this approach, 4 types of models were developed, being divided in 2 groups: (i) type of elements used in the model (shell or solid); and (ii) the complexity of the models. The simplified model considered only the thin aluminum plate (target), while the complete model considered the set used in the experimental setup (steel frame, aluminum clamp and plate) . . .

ABSTRACT: Energy flow analysis (EFA) can be used effectively to predict structural vibration in the medium-to-high frequency ranges. In this study, the energy flow finite element method (EFFEM), based on EFA, was used to predict the vibrations of a reinforced cylindrical structure in water. The predicted results of the
vibrational energy density for the structure were compared with corresponding experimental results. The structure was divided into several subsystems in the experiment, with several accelerometers attached to each subsystem. The input power excited into the experimental structure was measured using an impedance-head adhered to an exciter. Measured input power was used to predict vibration of the reinforced cylindrical structure by EFFEM in water for comparing experimental and numerical results. A comparison between the experimental and predicted results for the vibrational energy density showed that EFFEM was an effective tool for predicting structural vibration.

ABSTRACT: Owing to the existence of the flow field boundary, the shock wave load near the boundary is different from the free field shock wave load. In the present paper, the hull plate load subjected to underwater shock wave is investigated based on wave motion theories; in addition, the experimental study of the hull plate load is carried out. According to the theoretical analysis of the hull plate pressure, we find that the hull plate pressure oscillates repeatedly and decays rapidly with time passing, the maximum hull plate pressure is $2/(1+n)$ times the maximum free field pressure, where $n$ is the ratio of impedance, and the impulse is much smaller than the free field impulse. Compared with the experimental study, the theoretical results agree well with the experimental data.

ABSTRACT: In this paper, a numerical model on fluid-structure interaction is established and the validation of the model is carried out. The doubly asymptotic approximation for external domain is used to model the external fluid, the doubly asymptotic approximation for internal domain is used to model the internal fluid and the nonlinear finite element software ABAQUUS is employed to model the structure. Based on the numerical model, the influence of internal fluid to the dynamic response of double ring-stiffened cylindrical shell is investigated. The main results are as follows. Compared with the analytic solution, the oscillation period and amplitude of late time response obtained by the first order doubly asymptotic approximation decrease. But, the solution of the second order doubly asymptotic approximation agrees well with the analytic solution. The existence of internal fluid makes the plastic deformation and velocity response of double ring-stiffened cylindrical shell decrease.
ABSTRACT: In this paper, a numerical method is established to analyze the response of fluid-filled structure to underwater explosion with cavitation. The method is illustrated. In the present implementation, the second-order doubly asymptotic approximation (DAA2) other than curved wave approximation (CWA) is used to simulate non-reflecting boundary. Based on the method, the difference between DAA2 non-reflecting boundary and CWA non-reflecting boundary is investigated; then, the influence of internal fluid volume and the influence of cavitation on dynamic response of spherical shell are analyzed. Compared with CWA non-reflecting boundary, DAA2 non-reflecting boundary treats added mass effects better. When the internal fluid is full, the displacement and velocity of spherical shell decrease, but, when the internal fluid is half, the displacement and velocity of spherical shell increase. The effect of cavitation is more obvious at the trailing point than at the leading point of spherical shell.

ABSTRACT: High-pressure shock performance of sandwich composites consisting of nano-scale core-shell rubber (CSR) toughened E-glass Vinyl-Ester face-sheets and Corecell® A500 (Gurit (USA) Inc., Bristol, Rhode Island, USA) foam was studied using a shock tube apparatus. The core material and thickness, as well as overall specimen dimensions, were held constant, with the only difference arising in the resin system used during the infusion. The non-core-shell rubber toughened resin system (Non-CS drift) consisted of a vinyl-ester resin only, while the CSR toughened resin consisted of the same vinyl-ester resin, but with Kane Ace MX 153 CSR particles added to the vinyl-ester resin system. Prior to the shock tube experiments, the quasi-static and dynamic constitutive behaviour of the face-sheets (tensile/compressive) and foam (compressive) was evaluated. During the shock tube testing, a high-speed photography system coupled with the optical technique of digital image correlation was utilized to capture the real-time deformation process, as well as mechanisms of failure in the sandwich composites. Post-mortem analysis was also carried out to evaluate the overall shock performance of these configurations. Results indicated that adding CSR particles to sandwich composites aids in dispersing the initial shock wave loading, thus reducing the overall deflection, strain, and velocity and improving the overall blast resistance of the structure.

ABSTRACT: A numerical simulation has been carried out to examine the response of steel plates with different arrangement of stiffeners and subjected to noncontact underwater explosion (UNDEX) with different shock loads. Numerical analysis of the underwater explosion phenomena is implemented in the nonlinear finite element code ABAQUS/Explicit. The aim of this work is to enhance the dynamic response to resist UNDEX. Special emphasis is focused on the evolution of mid-point displacements. Further investigations have been performed to study the effects of including material damping and the rate-dependant material properties at different shock loads. The results indicate that stiffeners configurations and shock loads affect greatly the overall performance of steel plates and sensitive to the materials data. Also, the numerical results can be used to obtain design guidelines of floating structures to enhance resistance of underwater shock damage, since explosive tests are costly and dangerous.

Abstract: This paper provides direct technical support to the explosion-resistance design by considering both the shock wave and jet load simultaneously and taking into account of the effect of double shell structure types and sizes during the underwater near-field explosion. Based on the bubble pulsation analysis using Eulerian method in the vicinity of a rigid wall and the principle of energy equivalence, the dynamic response of a double shell structure subjected to underwater near-field explosion is numerically simulated. The jet load is then simplified and applied after the shock wave by using the MSC.Dytran software subroutine. Models with different structural types and sizes are also calculated and an optimal solution set which targets both the weight of the structure and the explosion-resistance capability is obtained via the multi-objective optimization approach. The results show that the optimum thickness of the support structure can be determined when the thickness of outer and inner shells and the distance between them are constant. Meanwhile, Y-frame double shell structures tend to provide higher explosion-resistance capability when the weight of structure is constant.

Abstract: The great use of circular cylindrical shells for conveying fluid in modern industrial applications has made of them an important research area in applied mechanics. Many researchers have studied this problem, however just a reduced number of these works have as object the analysis of orthotropic shells. Although most investigations deal with the analysis of elastic isotropic shells in contact with internal and external quiescent or flowing fluid, several modern and natural materials display orthotropic properties and also stiffened cylindrical shells can be treated as equivalent uniform orthotropic shells. In this work, the influence of internal flowing fluid on the dynamic instability and non-linear vibrations of a simply supported orthotropic circular cylindrical shell subjected to axial and lateral time-dependent loads is studied. To model the shell, the Donnell’s non-linear shallow shell theory without considering the effect of shear deformations is used. A model with eight degrees of freedom is used to describe the lateral displacements of the shell. The fluid is assumed to be incompressible and non-viscous and the flow to be isentropic and irrotational. The Galerkin method is applied to derive the set of coupled non-linear ordinary differential equations of motion which are, in turn, solved by the Runge-Kutta method. The obtained results show that the presence of the internal fluid and material properties have a great influence on the vibration characteristics of the shell.

Abstract: In the paper nonlinear vibrations of a drill string’s section in a supersonic gas flow are studied. The drill string is modelled in the form of a circular cylindrical shell under the effect of a longitudinal compressing load and torque. In contrast to the previous research, pressure of an unperturbed gas is defined.
nonlinearly in the third approximation. The eighth order partial differential equation describing the motion of the shell reduces to a nonlinear system of ordinary differential equations with application of the Bubnov-Galerkin technique. An implicit Runge-Kutta method is applied to construct modes of vibrations.

ABSTRACT: An experimental investigation on deformation shape of a cylindrical shell with internal medium subjected to lateral contact explosion was carried out briefly. Deformation shapes at different covered width of lateral explosive were recovered experimentally. Based on the experimental results, a corresponding analytical approach has been undertaken with rigid plastic hinge theory. In the analytical model, the cylindrical shell is divided into end-to-end rigid square bars. Deformation process of the cylindrical shell is described by using the translations and rotations of all rigid square bars. Expressions of the spring force, buckling moment, and deflection angle between adjacent rigid square bars are conducted theoretically. Given the structure parameters of the cylinder and the type of the lateral explosive charge, deformation processes and shapes are reported and discussed using the analytical approach. A good agreement has been obtained between calculated and experimental results, and thus the analytical approach can be considered as a valuable tool in understanding the deformation mechanism and predicting the deformation shapes of the cylindrical shell with internal medium subjected to lateral contact explosion. Finally, parametric studies are carried out to analyze the effects of deformation shape, including the covered width of the lateral explosive, explosive charge material, and distribution of initial velocity.

ABSTRACT: Contemporary nuclear submarines are built with double hulls which enhance the protection against explosive attacks. As the two hulls are separated by a distance (stand off), blast loading on the inner hull diminishes significantly. Thus, warheads fitted to underwater weapons with limited quantity of explosive become ineffective. In the present study, an attempt is made to quantify the enhanced protection to the underwater vessels due to double hull construction, through Explosion Bulge Test (EBT) experiments. Four different cases of air back up, water back up, partial water back up and free flood water back up are studied in the EBTs. The extent of reduction in damage to the double hulled vessel under various modes of back up are studied and discussed in this paper. Through these experiments, it is established that there is a significant reduction in damage from 22.5 to 63% to the hull when compared to air back up depending on different test conditions of water back up. The response of double hull to proximity explosion with air and water back up is simulated using a Finite Element (FE) model and compared.

Shukla (Dynamics Photomechanics Laboratory, Department of Mechanical, Industrial and Systems Engineering, University of Rhode Island, Kingston, RI, 02881, USA), “Shock-initiated buckling of carbon/epoxy composite tubes at sub-critical pressures”, Experimental Mechanics, April 2015, 10.1007/s11340-015-0033-1

ABSTRACT: A comprehensive investigation on the implosion of composite cylinders subjected to a nearby explosion is performed. Experiments are conducted in a large pressure vessel, designed to provide constant hydrostatic pressure throughout the event. Carbon fiber/epoxy filament-wound tubes are studied with constant hydrostatic pressure and varying charge standoff distances to determine the effect of the explosive loading on the mechanisms of collapse. 3-D Digital Image Correlation (DIC) is used to capture the full-field displacements and velocities during the implosion event, and to characterize the initial dynamic response of the tube. Dynamic pressure transducers measure the shock waves generated by the explosive and also the pressure pulse generated by the collapse. Results show that different magnitudes of explosive loading produce drastic differences in the way implosions are initiated, and in the extent of damage to the structure. Experiments with strong explosive loading show immediate collapse of the tube upon the arrival of shock wave. Relatively smaller explosive loading result in collapses due to the additional bubble pulse loading, or after accumulating damage for extended periods of time.

ABSTRACT: We investigate the dynamic stability of a pipe that conveys fluid, clamped or pinned at one end and with an intermediate support, thus exhibiting an overhang. The model of the pipe incorporates both Euler–Bernoulli and Bresse–Timoshenko schemes as well as transverse inertia. Material and external damping mechanisms are taken into account, while the conveyed fluid is supposed to be in fully turbulent flow. The pipe can rest on a linear elastic Winkler soil. The influence of all the physical quantities and of the overhang length on the critical velocity of the fluid front is investigated. Some numerical results are presented and discussed.

Dynamic acousto-elastic testing is applied to a mixture of lipid-coated microbubbles in water. A dynamic
change of ambient pressure is produced by a 16 kHz pressure wave having a peak pressure amplitude of 28 kPa. The induced changes of phase velocity and attenuation are captured by a sequence of short ultrasound pulses with a center frequency of 4 MHz. As a consequence of the dispersion brought about by the resonance of microbubbles at a frequency close to 2 MHz, time-domain approaches like the cross-correlation method are shown to be unsuited to determine the variation in ultrasound wavespeed. A frequency-domain analysis shows that the acousto-elastic effect (first order pressure derivative of ultrasound phase velocity) depends on the ultrasound frequency. The acousto-elastic effect tends to that measured in water for an ultrasound frequency above the resonance frequency of microbubbles, while it is two orders of magnitude larger for an ultrasound frequency close to or below the resonance frequency of microbubbles. Besides the large magnitude of the acousto-elastic effect observed for an ultrasound frequency below the resonance frequency of microbubbles, the first order pressure derivative of ultrasound phase velocity is negative. This supports the occurrence of shell buckling of lipid-coated microbubbles induced by the 16 kHz pressure wave.

ABSTRACT: The dynamic instability of the parabolic shells in a supersonic gas flow is analyzed numerically. Such structures describe a rocket fairing. Finite degrees of freedom dynamical system is obtained by the assumed-modes method to describe the shell motions. The numerical approach for calculations the modes of the shell self-sustained vibrations is suggested. The Mach numbers range of the shell dynamic instability is analyzed numerically. The influence of the paraboloid height on the regions of the dynamic instability is analyzed. The frequencies of the self-sustained vibrations are investigated. The effect of the shell boundary conditions on the regions of the dynamic instability is analyzed.

The fluid forces are described by the three-dimensional inviscid potential flow. The influences of angular flow on the critical axial velocity and the thermal loads are determined by the thermo-elastic theory. The numerical analyses are conducted by a zero-level contour method. The study shows the effects of annular gaps and boundary conditions on stability of shells. The influences of angular flow on the critical axial velocity and axial flow on the critical annular velocity are discussed. Moreover, the thermal loads decrease the critical flow velocity and the critical temperature rise is found.

10.1016/j.tws.2016.04.009

ABSTRACT: The free vibration and instability characteristics of nanoshells made of functionally graded materials (FGMs) with internal fluid flow in thermal environment are studied in this paper based upon the first-order shear deformation shell theory. In order to capture the size effects, Mindlin's strain gradient theory (SGT) is utilized. The mechanical and thermal properties of FG nanoshell are determined by the power-law relation of volume fractions. The Knudsen number is considered to analyze the slip boundary conditions between the flow and wall of nanoshell, and the average velocity correction parameter is used to obtain the modified flow velocity of nano-flow. The governing partial differential equations of motion and associated boundary conditions are derived by Hamilton's principle. An analytical solution method is also employed to solve the
governing equations under the simply-supported end conditions. Then, some numerical examples are presented to investigate the effects of fluid velocity, longitudinal and circumferential mode numbers, length scale parameters, material properties, temperature difference and compressive axial loads on the natural frequencies, critical flow velocities and instability of system.

ABSTRACT: Very flexible aircraft with high aspect ratio wings subjected to aerodynamic loads undergoes large deformation, which will lead to distinct changes on the mass distributions, stiffness characteristics and aerodynamic characteristics of the complete aircraft. The aeroelasticity and flight dynamics of such aircrafts are nonlinear and the linear elastic theory model cannot be used. A new method is developed for the analysis of nonlinear aeroelasticity and flight dynamics of very flexible aircraft through combining the co-rotational beam theory with the modified ONERA dynamic stall model. Based on a form of co-rotational technique which is external to the element, a spatial two-node beam element, which depicts the geometrically nonlinear dynamic characteristics of the flexible wing, is developed. Both tangential stiffness matrix and mass matrix of the beam element are formulated to establish the nonlinear dynamic equations. In addition, the modified ONERA dynamic stall model is adapted to evaluate the unsteady nonlinear aerodynamic loading of the very flexible wing. Using the present method, the nonlinear aeroelastic response, trim and stability characteristics of a very flexible aircraft are predicted in this paper. The obtained results show a good agreement to the literature, which indicates that the present method is accurate and efficient.

ABSTRACT: The primary function of a heart valve is to allow blood to flow in only one direction through the heart. Triangular thin-shell finite element formulation is implemented, which considers only translational degrees of freedom, in three-dimensional domain to simulate heart valves undergoing large deformations. The formulation is based on the nonlinear Kirchhoff thin-shell theory. The developed method is intensively validated against numerical and analytical benchmarks. This method is added to previously developed membrane method to obtain more realistic results since ignoring bending forces can result in unrealistic wrinkling of heart valves. A nonlinear Fung-type constitutive relation, based on experimentally measured biaxial loading tests, is used to model the material properties for response of the in-plane motion in heart valves. Furthermore, the experimentally measured linear constitutive relation is used to model the material properties to capture the flexural motion of heart valves. The fluid structure interaction solver adopts a strongly coupled partitioned approach that is stabilized with under-relaxation and the Aitken acceleration technique.

ABSTRACT: Flows with moving boundaries and interfaces (MBI) include fluid–structure interaction and a number of other classes of problems, such as fluid–object interaction, fluid–particle interaction, free-surface and multi-fluid flows, and flows with solid surfaces in fast, linear or rotational relative motion. These problems are
frequently encountered in engineering analysis and design, pose some of the most formidable computational challenges, and have a common core computational technology need. Bringing solution and analysis to them motivated the development of a good number of core computational methods and special methods targeting specific classes of MBI problems. This chapter is an overview of some of those core and special methods, with a focus on computational examples from the ST-VMS and ALE-VMS methods and special methods developed in conjunction with the two.

“Multiscale methods for gore curvature calculations from FSI modeling of spacecraft parachutes”,
ABSTRACT: There are now some sophisticated and powerful methods for computer modeling of parachutes. These methods are capable of addressing some of the most formidable computational challenges encountered in parachute modeling, including fluid–structure interaction (FSI) between the parachute and air flow, design complexities such as those seen in spacecraft parachutes, and operational complexities such as use in clusters and disreefing. One should be able to extract from a reliable full-scale parachute modeling any data or analysis needed. In some cases, however, the parachute engineers may want to perform quickly an extended or repetitive analysis with methods based on simplified models. Some of the data needed by a simplified model can very effectively be extracted from a full-scale computer modeling that serves as a pilot. A good example of such data is the circumferential curvature of a parachute gore, where a gore is the slice of the parachute canopy between two radial reinforcement cables running from the parachute vent to the skirt. We present the multiscale methods we devised for gore curvature calculation from FSI modeling of spacecraft parachutes. The methods include those based on the multiscale sequentially-coupled FSI technique and using NURBS meshes. We show how the methods work for the fully-open and two reeved stages of the Orion spacecraft main and drogue parachutes. References listed at the end of the paper:

ABSTRACT: Forced oscillations of flexible plates with a longitudinal, time dependent load acting on one plate side are investigated. Regular (harmonic, subharmonic and quasi-periodic) and irregular (chaotic) oscillations appear depending on the system parameters as well as initial and boundary conditions. In order to achieve highly reliable results, an effective algorithm has been applied to convert a problem of finding solutions to the hybrid type partial differential equations (the so-called von Karman form) to that of the ordinary differential equations (ODEs) and algebraic equations (AEs). The obtained equations are solved using finite difference method with the approximations $0(h^4)$ and $0(h^2)$ (in respect to the spatial coordinates). The ODEs are solved using the Runge–Kutta fourth order method, whereas the AEs are solved using either the Gauss or relaxation methods. The analysis and identification of spatio-temporal oscillations are carried out by investigation of the series $w(t), w(t), \text{phase portraits } w(t), w(t) \text{ and the mode portraits in the planes } w(t), w(t) \text{ and in the space } w(t), w(t) \text{ and in the space } w(t), w(t) \text{ as well as the Poincare sections and pseudo-sections.}

ABSTRACT: Determination of the chaos onset in some mechanical systems with several equilibrium positions are analyzed. Namely, the snap-through truss and the oscillator with a nonlinear dissipation force, under the external periodical excitation, are considered. Two approaches are used for the chaos onset determination. First,
Pade and quasi-Pade approximants are used to construct closed homoclinic trajectories for a case of small dissipation. Convergence condition used earlier in the theory of nonlinear normal vibration modes as well conditions at infinity make possible to evaluate initial amplitude values for the trajectories with admissible precision. Mutual instability of phase trajectories is used as criterion of chaotic behavior in nonlinear systems for a case of not small dissipation. The numerical realization of the Lyapunov stability definition gives us a possibility to observe a process of appearance and fast enlargement of the chaotic behavior regions if some selected parameters of the dynamical systems under consideration are changing.

ABSTRACT: A closed cylindrical shell with circular cross-section having constant stiffness and density and subjected to sign changeable loading and embedded into a temperature field is analyzed. Both Bubnov-Galerkin (with a higher approximation) and Fourier methods are applied to solve the derived nonlinear nondimensional partial differential equations. Among others, the novel scenario of transition from shell harmonic to chaotic vibrations via the collapse of quasi-periodic vibrations with one independent frequency and Hopf bifurcation is detected, illustrated and discussed. In addition, it is shown how for various intensities of the temperature field (including its absence) the increase of the loading yields qualitative changes in the investigated shell dynamics, and how chaotic zones are transmitted into periodic ones and vice versa.

ABSTRACT: A problem on chaotic vibrations of the Bernoulli–Euler beams is formulated. The wavelet transform was first applied to investigate the complex beam vibrations. The validity of results is provided by using two methods of solution, namely, the finite element method and finite difference method.

INTRODUCTION: The Fourier analysis, that is, the analysis based on the fast Fourier transform, is one of the most spread for investigating the chaotic dynamics of different physical nature. Its application for the distributed mechanical systems such as beams, plates, and shells is discussed in [1–8]. In addition, at present, the signal analysis based on the wavelet transform is rapidly progressing. In this paper, we demonstrate the advantage of this line that permits studying the processes of time variation in the vibration character on the basis of a frequency-time spectrum.

ABSTRACT: In this work regular and chaotic dynamics of cylindrical elastic and isotropic panels is studied. Geometrical nonlinearities are introduced following the Kármán hypothesis. A solution to PDEs is reduced to that of the corresponding ODEs via the second order Bubnov-Galerkin approach. A problem of approximation of the studied continuous system by a lumped one is discussed. It is shown that first order rough approximation reduces the problem to that of the Duffing equation analysis. Influence of the higher modes on the panel dynamics is studied. Scenarios of transition from regular to chaotic dynamics are detected and illustrated. The so-called vibration type charts of the cylindrical panels supported on the flexible and non-stretched in a tangent plane ribs versus geometrical and external excitation parameters are constructed and analyzed.

INTRODUCTION: One of the challenging directions of the continual system chaotic dynamics investigations is that of plates and shells dissipative dynamics, and in particular detection of the scenarios leading to chaos in those systems plays a crucial role both in theory and applications. Almost in all studied so far cases, the infinite dimensional objects (plates and shells) are modeled as one- and/or two-degree-of-freedom systems. In contrary, here we deal with the infinitely dimensional problem, which is solved by qualitatively different numerical approaches including the Bubnov-Galerkin method (BGM) and the Rita method (RM) in higher approximations as well as the Finite Difference Method (FDM) with various space coordinates partition. This approach will validate both suitability of the numerical algorithms as well allows to trace scenarios leading to chaos in continual mechanical systems.

SUMMARY: Non-linear dynamics of flexible rectangular plates subjected to external shear-harmonic load action is investigated. It is shown that the application of the classical and widely used Fourier analysis does not allow us to obtain a real picture of the frequency vibration characteristics in every time instant. On the other hand, the application of the wavelets approach enables us to follow frequency time evolutions. Our numerical results indicate that vibrations in different plate points occur with the same frequencies set although their power is different. Hence, the vibration characteristics can be represented by one arbitrarily taken plate point. Scenarios of transitions from regular to chaotic dynamics are illustrated and discussed including two novel scenarios not reported so far in the existing literature.

ABSTRACT: In the first part of the paper we propose a novel method devoted to the estimation of Lyapunov exponents using neural networks. In the referenced earlier attempts many approaches and algorithms have been proposed to compute the Lyapunov exponents, but in general almost all of them apply the algorithm proposed already by Benettin [1]. However, while studying non-linear dynamics of structural members (beams, plates and shells) it is of great importance to estimate the spectrum of Lyapunov exponents in an efficient way. This paper part addresses this problem. In the second paper part we illustrate and discuss the application of various types of wavelets to study non-linear dynamics of shells. The obtained PDEs are reduced to ODEs using the Finite Difference Method, which then are solved using the fourth-order Runge-Kutta method. In addition, the classical Fourier analysis versus the wavelet analysis is discussed.

References listed at the end of the paper:

ABSTRACT: In the first paper part we study the mathematical model of a two-layer cylindrical shell (with clearance between both shells) having constant stiffness and density and subjected to a periodic transversal load action. The derived mathematical model allows us to study non-linear dynamics of both structural members with regard to external load and internal interaction between the two layers, as well as the force action coming from the inside of the second cylinder. The developed mathematical model includes geometric non-linearity of both cylinders and their contact interactions. Differential equations governing the dynamics of both shells are solved by the Bubnov-Galerkin higher order approximation method, whereas the obtained Cauchy problem is solved using the fourth order Runge-Kutta method. Convergence of the Bubnov-Galerkin method versus the number of approximating series terms is considered. Namely, we solve the problem of two embedded cylindrical shells including their interaction as systems with an infinite number of degrees of freedom. In the second paper part chaotic dynamics of continuous multi-layer structural members in the form of flexible shallow spherical panels is analyzed. The PDEs governing panels dynamics are reduced to the Cauchy problem through the FDM (Finite Difference Method) of the second accuracy order, and then the ODEs obtained are analyzed via the fourth-order Runge-Kutta method. A novel scenario of transition from regular to chaotic panel dynamics is reported and illustrated. We develop approaches to detect and monitor spatial chaos, and then we illustrate how both timing and spatial chaos appears simultaneously. We show also how the two-layer structural member exhibits non-symmetric chaotic vibrations, which after transition into windows with periodic dynamics exhibit again symmetric vibrations.

References listed at the end of the paper:

ABSTRACT: We study the interaction of multi-layer packets consisting of beams, plates and shells, where there are gaps between the mentioned structural members. The proposed mathematical model takes into account various types of non-linearity: (i) geometrical (in the Kármán form); (ii) physical (layer material properties depend on the space co-ordinates, deformation intensity and time); (iii) design (it either switches on or off a contact between layers). Physical properties of the material can be different. The governing partial differential equations, boundary and initial conditions are obtained using Hamilton’s variation principle. The so far obtained boundary value problem is then reduced to the Cauchy problem by the following methods: FDM (Finite Difference Method) and the hybrid method matching FEM (Finite Element Method) and the Bubnov-Galerkin method with high order approximations. The obtained initial value problem is solved using the 4th, 6th and 8th Runge-Kutta techniques. It will be shown that those approaches are necessary to get the reliable results of our problem exhibiting strong non-linearity effects and chaotic vibrations. It should be emphasized that the obtained results are studied for all engineering required intervals of changes of the input load parameters, i.e. its amplitude and frequency (charts of vibration-type are constructed). Each output signal is analyzed via phase and modal portraits, Poincarè maps, auto-correlation functions, Fourier spectra as well as wavelets. In the latter case the efficiency of different wavelets is illustrated and discussed. Furthermore, we propose a novel approach to quantify regular and chaotic vibrations via signs estimation of the Lyapunov exponents. Different scenarios of transition from regular to chaotic dynamics exhibited by the studied objects for the mentioned types of non-linearity are illustrated and discussed. We show how the non-linearity type leads to a dramatic change of the transition from regular to chaotic vibrations. In addition, the influence on the non-linear vibrations of the studied multi-layer continuous systems of the non-linearity type, layer number, boundary conditions, layer thickness as well as magnitude of the gap between layers is investigated and reported.

ABSTRACT: In this paper chaotic vibrations of flexible plates of in finite length are studied. The Kirchhoff Love hypotheses are used to derive the nondimensional partial differential equations governing the plate dynamics. The finite difference method (FDM) and finite element method (FEM) are applied to validate the numerical results. The numerical analysis includes both standard (time histories, fast Fourier Transform, phase portraits, Poincaré sections, Lyapunov exponents) as well as wavelet-based approaches. The latter one includes the so called Gauss 1, Gauss 8, Mexican Hat and Morlet wavelets. In particular, various plate dynamical regimes including the periodic, quasi-periodic, sub-harmonic, chaotic vibrations as well as bifurcations of the plate are illustrated and studied. In addition, the convergence of numerical results obtained via different wavelets is analyzed.

ABSTRACT: Chaotic vibrations of rectangular spherical shells subjected to the action of periodic load have been rarely analyzed. This work extends investigations initiated in the works by Awrejcewicz et al. [1-3].

References listed at the end of the paper:
Usually the data provided by numerical experiments are presented in time domain. In other words, we take time as an independent co-ordinate, and amplitude as a dependent co-ordinate, and the studied signal as analyzed through its amplitude-time representation. However, in order to understand deeply non-linear continuous systems subjected to various types of load actions and in order to fully understand the occurring dynamics, we have to apply the information hidden in the spectral signal characteristics. The Fourier transformation has been applied for a long time. However, it has been demonstrated recently that the Fourier analysis (FFT) is reliable only for the study of frequency components of stationary processes, i.e. the processes which through the whole period of investigation keep constant frequency components in time. It happens that in particular the dynamics of continuous mechanical systems may exhibit quite complicated output, and their frequency characteristics may change strongly in time. This is why in spite of the standard Fourier approach the wavelet analysis is applied allowing us to detect and understand many interesting non-linear phenomena of the mentioned mechanical systems.

Chaotic dynamics of structural members has been investigated by many researchers [1-10]. In this work we propose a novel approach to study non-linear vibrations of a plate based on the neural network approach and we analyze dynamics of flexible shells with constant stiffness and density subjected to harmonic load action. In the latter case mathematical model is built on the Kirchhoff-Love hypothesis and taking into account non-linear relation between deformation and displacement in the von Kármán form. This approach yields a system of non-linear PDEs regarding the deflection function and stresses (Airy’s function) as well as the system of equations regarding displacements [11]. We use further FDM with approximation $O(h^2)$ and BGM in higher approximations, which allows to study the system with infinite numbers of degrees of freedom without any truncation of the obtained system of ODEs, which is solved via the fourth-order Runge-Kutta method.

ABSTRACT: The aim of this chapter is to present a study of periodic and chaotic dynamics of plates and shells and weak turbulent behavior exhibited by these solid structural members modeled as 2D infinite objects. Besides the new results obtained with respect to the transition from a regular to weak turbulent and weak hyper turbulent behavior, we also present novel methods and approaches to get reliable and validated results of
numerical analysis of nonlinear partial differential equations. In particular, besides the standard numerical techniques for chaos monitoring, new effective approaches are presented and applied including the wavelet-based analysis, charts of vibration regimes, computation of the spectra of Lyapunov exponents via generalization of the classical Benettin’s approach, and application of the neural network technique. This common strategy aimed at numerical computations through various types of robust discretization allowed us to obtain novel scenarios of transition from regular/laminar (periodic, quasiperiodic) to spatiotemporal chaotic (weak turbulent) dynamics of flexible shells either parametrically excited (Sect. 2) or through the periodic shear load action in the shell volume unit (Sect. 3), flexible multilayer rectangular (Sect. 4) and cylindrical shells with gaps (Sect. 5), as well as a flexible plate of infinite length (Sect. 6).

ABSTRACT: In this work a mathematical model of chaotic vibrations of flexible curvilinear Euler-Bernoulli beams embedded into temperature and electric fields is proposed. In particular, the influence of the curvature parameter k_\alpha on the vibration beam regimes under the action of transversal harmonic load is investigated. First, charts associated with the signs of the Lyapunov exponents versus two control parameters \{q_0, w_p\}, where \(q_0\) , \(w_p\) is the amplitude and the frequency of harmonic excitation, respectively, are constructed. Dynamic regimes and transitions of chaos-hyperchaos (two positive Lyapunov exponents), hyper-hyperchaos (three positive Lyapunov exponents), and deep chaos (four positive Lyapunov exponents) are reported. Second, different charts of the vibration character estimation are compared with each other showing remarkable coincidence. Finally, it has been shown that the electric field applied to both sides of the straight line beam negligibly influences chaotic vibrations of the studied beam.

ABSTRACT: We investigate chaotic vibrations of flexible spherical rectangular shells loaded harmonically and explain the phenomenon of transition from symmetric to asymmetric vibrations. Vibration-type charts are given regarding two control parameters: amplitude $q_0$ and frequency $\omega_p$ of the uniformly distributed periodic excitation. Furthermore, we detected and illustrated how the so called temporal–space chaos is developed following the transition from regular to chaotic system dynamics.

ABSTRACT: We investigate chaotic vibrations of flexible spherical rectangular shells loaded harmonically via the boundary conditions. In the first part of the paper we consider one-layer shell made from an isotropic and homogeneous material. The second part addresses non-linear dynamics of multi-layer shells, taking into account gaps between the layers (design non-linearity). Contact pressure between the layers was explicitly defined. Phase portraits, Fourier power spectra and wavelet spectra were constructed and investigated. In addition, an appropriate choice of the wavelets suitable to study the state transitions listed at the end of the paper: [1] Sethna P.R. Yang, X.L. Krysko, “Regular and chaotic dynamics of flexible plates”, Shock and Vibration, Vol. 2014, Article ID 937967, 8 pages, http://dx.doi.org/10.1155/2014/937967 ABSTRACT: Nonlinear dynamics of flexible rectangular plates subjected to the action of longitudinal and time periodic load distributed on the plate perimeter is investigated. Applying both the classical Fourier and wavelet analysis we illustrate three different Feigenbaum type scenarios of transition from a regular to chaotic dynamics. We show that the system vibrations change with respect not only to the change of control parameters, but also to all fixed parameters (system dynamics changes when the independent variable, time, increases). In addition, we show that chaotic dynamics may appear also after the second Hopf bifurcation. Curves of equal deflections (isoclines) lose their previous symmetry while transiting into chaotic vibrations.

ABSTRACT: We present chaotic dynamics of flexible curvilinear shallow Euler–Bernoulli beams. The continuous problem is reduced to the Cauchy problem by the finite-difference method of the second-order accuracy and finite element method (FEM). The Cauchy problem is solved through the fourth- and sixth-order Runge–Kutta methods with respect to time. This preserves reliability of the obtained results. Non-linear dynamics is investigated with the help of a qualitative theory of differential equations. Frequency power spectra using fast Fourier transform, phase and modal portraits, autocorrelation functions, spatiotemporal dynamics of the beam, 2D and 3D Morlet wavelets, and Poincaré sections are constructed. Four first Lyapunov exponents are estimated using the Wolf algorithm. Transitions from regular to chaotic dynamics are detected, illustrated and discussed. Depending on signs of four Lyapunov exponents the chaotic, hyper chaotic, hyper-hyper chaotic, and deep chaotic dynamics is reported. Curvilinear beams are treated as systems with an infinite number of degrees of freedom. Charts of vibration character, elastic–plastic deformations, and stability loss zone versus control parameters of the studied beams are reported.

The aim of the paper was to analyze the given nonlinear problem by different methods of computation of the Lyapunov exponents (Wolf method, Rosenstein method, Kantz method, the method based on the modification of a neural network, and the synchronization method) for the classical problems governed by differential equations (Hénon map, hyperchaotic Hénon map, logistic map, Rössler attractor, Lorenz attractor) and with the use of both Fourier spectra and Gauss wavelets. It has been shown that a modification of the neural network method makes it possible to compute a spectrum of Lyapunov exponents, and then to detect a transition of the system regular dynamics into chaos, hyperchaos, and others. The aim of the comparison was to evaluate the considered algorithms, study their convergence, and also identify the most suitable algorithms for specific system types and objectives. Moreover, an algorithm of calculation of the spectrum of Lyapunov exponents based on a trained neural network has been proposed. It has been proven that the developed method yields good results for different types of systems and does not require a priori knowledge of the system equations.

ABSTRACT: Parametric non-linear vibrations of flexible cylindrical panels subjected to additive white noise are studied. The governing Marguerre equations are investigated using the finite difference method (FDM) of the second-order accuracy and the Runge-Kutta method. The considered mechanical structural member is treated as a system of many/infinite number of degrees of freedom (DoF). The dependence of chaotic vibrations on the number of DoFs is investigated. Reliability of results is guaranteed by comparing the results obtained.
using two qualitatively different methods to reduce the problem of PDEs (partial differential equations) to ODEs (ordinary differential equations), i.e. the Faedo-Galerkin method in higher approximations and the 4th and 6th order FDM. The Cauchy problem obtained by the FDM is eventually solved using the 4th-order Runge-Kutta methods. The numerical experiment yielded, for a certain set of parameters, the non-symmetric vibration modes/ forms with and without white noise. In particular, it has been illustrated and discussed that action of white noise on chaotic vibrations implies quasi-periodicity, whereas the previously non-symmetric vibration modes are closer to symmetric ones.

A.L. Smirnov and E.A. Dolgova (Saint Petersurg State University, Russia), “Vibrational spectra of thin elliptic plates”, ICMAMS 2018, First International Conference on Mechanics of Advanced Materials and Structures, Turin, June 17-20, 2018
ABSTRACT: Thin plates of different shapes are used as structural components in almost all engineering
applications, where high strength, stiffness and light weight materials are highly needed. The aim of this
research is to study free transverse vibrations of an elliptic thin plate with a varying eccentricity and a plate with
an elliptic cutout with the same eccentricity. Plates of such shape are widely used not only in engineering but
also in biomechanical modeling. For example, for all human eyes the Lamina Cribrosa (anatomical structure)
appears as an elliptical plate with multiple holes.
Both analytical and numerical methods are used to examine the problem. The analytical solution is represented
as a combination of Mathieu functions. For plates with small eccentricity and/or small central elliptic cutout
asymptotic methods are used to describe the effect of the eccentricity and cutout on the vibrational spectra.
The difference between vibrations of a circular and an elliptic plate is the following. For a circular plate a
vibrational mode can be expressed by one particular solution of the differential equation governing vibrations,
for an elliptic plate all appropriate particular solutions should be summed up to express even one vibrational
mode. One should remember it when consider the perturbation of the vibrational spectrum of a circular shell
with non-zero eccentricity.
For elliptic plates of constant thickness and mass the effect of the eccentricity is the following: i) all frequencies
increase with the eccentricity, but with different rate, ii) double frequencies of non-axisymmetric vibrations of a
circular plate split into two, the lower frequency corresponds to the mode stretched along the long semi-axis, the
effect on the frequencies for small values of the axis ratio (up to 1:2) is linear with the high accuracy, iii) lower
frequencies go up with the eccentricity faster, as a result for some values of the eccentricity the mode order
Changes.
Frequencies and modes were also found by finite element method using the package ANSYS 18.1. The results were compared with those obtained by other authors who used Rayleigh-Ritz and other numerical methods.

ABSTRACT: A series of tests was conducted to investigate the web crippling behaviour of cold-formed lean duplex stainless steel (LDSS) tubular sections. The LDSS had two grades, including EN 1.4062 and EN 1.4162. The tests were performed under three different conditions of concentrated end bearing loads, namely, the loading conditions of End-One-Flange (EOF), the End-Two-Flange (ETF) and end loading (EL). The loading conditions of EOF and ETF are specified in the American and Australian/New Zealand cold-formed stainless steel design specifications, while the loading condition of EL simulated the floor joist members positioned on a solid foundation under concentrated end bearing load. The test specimens were mainly failed by web crippling. The test strengths were compared with the predicted strengths that calculated by the stainless steel design specifications, including the American Society of Civil Engineers (ASCE) Specification, Australian/New Zealand Standard (AS/NZS) and European Code (EC). In addition, the web crippling strengths predicted by the North American Specification (NAS) for cold-formed carbon steel structures and using the design equations proposed in the literature for cold-formed duplex stainless steel tubular sections were also compared with the test strengths. It was found that the predicted strengths calculated by the ASCE, AS/NZS and EC specifications are conservative and reliable for LDSS sections under the three different concentrated end bearing loads. The predictions by NAS and proposed equations in the literature are generally less conservative compared with those by ASCE, AS/NZS and EC. However, the predictions by NAS are found to be unconservative and not reliable for the loading condition of ETF.

ABSTRACT: Multi-cell concrete-filled steel tubular (CFST) column is a type of composite members developing from conventional CFST columns. Featuring greater cross-sectional dimensions and the use of internal webs to separate inner concrete into smaller isolated cells, multi-cell CFST columns have been used in super high-rise buildings recently as the main vertical load bearing members. However, existing research on CFST members is mainly focused on conventional single-cell CFST members. To fill this research gap, this paper numerically investigates the mechanical performance of hexagonal multi-cell CFST stub columns under axial compression. A finite element analysis (FEA) model was initially established to simulate the mechanical performance of hexagonal multi-cell CFST columns. The FEA model was validated against existing experimental data. The mechanical performance of the multi-cell CFST columns were analysed, including the full-range load versus deformation relationships, the stress distributions of the main components and the distribution of contact stress on each concrete cell. A parametric study was then conducted to investigate the sensitivity of various geometric and material parameters on the compressive behaviour of multi-cell CFST columns. Finally, analytical formulae were derived to predict the axial compressive ultimate strength of hexagonal multi-cell CFST columns. The methods were found to be acceptable with reasonably good accuracy.

ABSTRACT: The following paper presents a Finite Element formulation based on the Generalized Beam Theory (GBT), to analyse the buckling behaviour of isotropic conical shells under various loading and boundary conditions. The formulation offers the solution of the 1st order analysis from which the pre-buckling stresses are computed, including stress concentrations, and the linear (bifurcation) buckling solution. Due to the variable cross-section of conical shells, the mechanical and geometrical properties are no longer constant along the bar’s axis as they are in the case of cylindrical structures and thin-walled prismatic bars. Special focus is given to the effect of the pre-buckling stress concentrations and non-conventional cross-section deformation modes. The proposed formulation is validated by comparing results obtained from GBT and Shell Finite Element Analyses.

ABSTRACT: In recent years, hierarchical structures were popularly investigated due to its significant promotion on structural strength and stiffness. In this study, the concept of vertex-based hierarchy is incorporated into multi-cell square tubes by replacing every vertex with miniature cell itself. Mechanical performance of vertex-based hierarchical vs. square thin-walled multi-cell structure were conducted theoretically and numerically, mainly in terms of total energy absorption (TEA), crush force efficient (CFE) and fluctuation degree. A static theoretical model was constructed for vertex-based structures based on classic angle-fold element. The equation of half-wave length as well as the mean force in each fold was constructed based on the Minimal Energy Principle. Then, detailed numerical simulations were carried out by means of explicit dynamic finite element method. Based on these, further parametric studies with different scale ratios were performed and the influence of geometric configuration was determined. In addition, the explanations for promotion have been given. As the results confirmed that comparing with the conventional multi-cell structure, the vertex-based hierarchical one can evidently improve the folding response with stable compression history. The scale ratio significantly influences the specific mean force. The wall thickness shows more sensitivity on mechanical performances. All these achievements pave a way of designing novel thin-walled and light-weight energy absorption device.

ABSTRACT: Material properties, residual stress distributions and cross-sectional behavior of cold-formed steel elliptical hollow sections are investigated in this study. Four cross-section series with the nominal section aspect ratio ranging from 1.65 to 3 were included in the experimental investigation. The material properties for each cross-section series and material properties distribution on half of the cross-section profile of a representative section were measured through tensile coupon tests. The distributions of bending and membrane residual stresses in both longitudinal and transverse directions were measured on the half-section profile of the same representative section. Initial local geometric imperfections were measured on five stub column specimens. Besides, stub column tests were conducted between fixed ends to ascertain the material properties of the complete cross-section in the cold-worked state as well as to study the structural behavior of cold-formed steel elliptical hollow section stub columns. In addition to experimental investigation, a finite element model was developed and verified against the test results, with which an extensive parametric study covering a broad range of cross-section geometries was carried out. Currently, there is no codified design rule for elliptical hollow section compression members. The stub column strengths obtained from experimental program and numerical analysis were only compared with the predicted strengths by the equivalent diameter method and equivalent rectangular hollow section approach proposed by previous researchers for design of hot-finished steel elliptical hollow sections, the existing traditional design rules originally developed for circular hollow section with equivalent diameter incorporated as well as the Direct Strength Method and the Continuous Strength Method that the equations were not calibrated for cold-formed steel elliptical hollow sections. The comparisons show that the Direct Strength Method offers the most accurate and reliable design strength predictions among the existing design methods, but further improvement remains possible. In this study, modifications on the Direct Strength Method and the Continuous Strength Method are proposed, which are shown to improve the accuracy of the design strength predictions.

ABSTRACT: This paper presents a method to calculate modal displacement, stress, and strain energy participation in shell finite-element eigen-buckling solutions of thin-walled structural members using Generalized Beam Theory (GBT). The method provides quantitative information that can be used to interpret coupled buckling in structural designs. A finite-element (FE) eigen buckling solution is transformed to a GBT solution, and equivalent GBT modal amplitudes representing the FE solution are retrieved. The modal displacement field, stress tensor and strain energy are retrieved using GBT modal amplitude field and applying GBT constitutive relationships between strain and stress. Theory and examples are provided.

ABSTRACT: Structural design formulae for beam-columns require accurate end points (i.e. accurate resistance predictions for pure compression and pure bending), should be of suitable form to capture the interaction between the different components of loading and should take due account of the influence of a moment gradient along the member length. However, existing design rules for stainless steel beam-columns do not fully capture the interaction responses observed in experiments and numerical simulations, and are often tied to inaccurate end points; the adopted equivalent uniform moment factors can also be unconservative in the case of high moment gradients. As a consequence, previous comparisons of stainless steel beam-column experimental and finite element results with codified strength predictions have often revealed a rather high degree of scatter. This prompted the present research, to develop improved design proposals for stainless steel square hollow section (SHS) and rectangular hollow section (RHS) beam-columns under moment gradients. To this end, revised design approaches are proposed firstly through the derivation of more accurate design interaction curves for stainless steel SHS and RHS beam-columns under uniform bending moment and then through the employment of more suitable equivalent uniform moment factors, underpinned by and validated against over 1500 test and numerical data points. The new design approaches are shown to lead to improved (safe-sided, accurate and consistent) resistance predictions for stainless steel SHS and RHS beam-columns under moment gradients over the current codified design rules. Finally, statistical analyses are performed to demonstrate the reliability of the proposed approaches, according to the requirements specified in EN 1990.

ABSTRACT: A finite element formulation is developed to predict the lateral torsional buckling resistance of plane frames with moment connections. The solution focuses on the simple characterization the elastic warping behavior of moment connections in a manner that allows them to interface seamlessly with existing beam buckling finite elements, thus providing means for realistically modelling the lateral torsional buckling of plane frames. Special attention is devoted to the joint rotation effects. The technique successfully captures the interaction between beams and columns of frames, an effect that is neglected in present design methodologies based on individual member checks. The solution is shown to provide lateral torsional buckling resistance predictions in very good agreement with shell based finite element solutions at a fraction of the modelling and computational effort. For typical frames that are laterally supported at the joints, the study suggests that present design methodologies that isolate the member from the rest of the structure provide conservative buckling resistance predictions. Conversely, for frames with no lateral restraints at some of the joints, the present solution predicts lateral torsional buckling resistances that are significantly different from those based on design standard equations, suggesting the need to account for interaction effects in such situations

The effects of warping on the postbuckling behaviour of thin-walled structures have been studied extensively. It is shown that circular openings may be represented for analysis purposes as an equivalent rectangular web, which adds to the deflection of the solid web beam. The additional deflection is a function of the ratio of opening diameter, h, to section depth, d, and also of the spacing of the openings. This paper presents derived formulae for the additional deflection of beams with circular web openings that are expressed as a function of the pure bending deflection of the unperforated beam. The formulae are calibrated against finite element models and against short span beam tests with opening diameters, h, of 0.6 h and 0.72 h, in which the additional deflection is mainly due to the effects of shear. Further simplified design formulae for additional deflection are also presented which are shown to be accurate for C-section beams with a span: depth ratio exceeding 15. It is also shown that circular openings may be represented for analysis purposes as an equivalent rectangle of width x depth equal to 0.75 h × h.

ABSTRACT: Face-to-face built-up cold-formed steel channel sections are becoming increasingly popular for column members in cold-formed steel structures; its applications include cold-formed steel trusses, space frames and portal frames. In such an arrangement, the independent buckling of the members is resisted by intermediate fasteners. In the literature, no research is available for such face-to-face built-up cold-formed steel columns. The issue is addressed herein. This paper presents the results of 36 experimental tests, conducted on face-to-face built-up cold-formed steel channel-sections covering a wide range of slenderess from stub to slender columns. A nonlinear finite element model is then described that shows good agreement with the experimental results. The finite element model includes material non-linearity, initial imperfections and modelling of intermediate fasteners. Both finite element and experimental results are compared against the design strengths calculated in accordance with the American Iron and Steel Institute (AISI), Australian and New Zealand Standards (AS/NZS) and Eurocode (EN 1993-1-3). The verified finite element model is used for the purposes of a parametric study comprising 90 models. The effect of fastener spacing on the axial strength was investigated. From the results of experiments and finite element investigations, it is shown that the design in accordance with the AISI & AS/NZS and Eurocode (EN 1993-1-3) is generally conservative by around 15%, however, AISI & AS/NZS and Eurocode (EN 1993-1-3) can be un-conservative by 8% on average for face-to-face built-up columns failed through local buckling.

ABSTRACT: Metallic circular tube with external uniform grooves has excellent behaviors on axial crashworthiness during axial compression because it can generate stable responses. In the present research, three novel energy absorbers are proposed based on uniform grooved tube (UGT), namely, depth gradient grooved tube (D-GGT), thickness gradient grooved tube (T-GGT) and coupling gradient grooved tube (C-GGT). A theoretical model considering both the depth and thickness gradients and an efficient numerical model based on axisymmetric assumption are put forward. Meanwhile, some quasi-static compression experiments are performed to validate the theoretical and numerical models. The results conclude that the deformation of gradient grooved tubes (GGTs) under axial buckling can be classified into two modes, namely, random asymptotic buckling (RAB) and sequential asymptotic buckling (SAB). Compared with UGT, the D-GGT has a slight improvement on the axial energy performance even though the sum of depth of thin-walled sections is constant; for T-GGT, a force-displacement curve with upward trend and an obvious improvement of energy absorption are observed; specially, the energy absorption characteristics of D-GGT and T-GGT will occur simultaneously when C-GGT is subjected to axial loading.

ABSTRACT: The dynamic responses of large-span space structures are significantly associated with some higher structural frequency modes. A proper finite element model with accurate modal damping ratios is a key factor in obtaining precise structural seismic responses in numerical analyses. The complex damping model is often used in frequency domain structural analyses because of its characteristics of constant modal damping
ratio with frequency and frequency-independent energy dissipation. Based on the five-parameter integer-order derivative method, a user subroutine of ABAQUS is developed to estimate the complex damping model in time-domain dynamic analyses. A shaking table test of a scaled and simplified single-layer reticulated dome is first conducted to validate the user subroutine. Detailed test data, including the identified natural frequencies and modal damping ratios, free vibration curves, and representative maximum responses, are summarized and compared with the corresponding finite element results using the complex damping model and a Rayleigh damping model. The comparisons indicate that the results of the complex damping model can yield a better estimation of the test data. Finally, the effect of the complex damping on the seismic responses of a single-layer reticulated dome is systematically studied by comparing the structural frequency properties and dynamic characteristic responses with those of Rayleigh damping. The results show that the complex damping model provides smaller structural modal damping ratio variation, lower ultimate seismic loading, and severer structural plastic developments.

ABSTRACT: The vibration and stability problems of functionally graded material (FGM) cylindrical shells subjected to external pressures with mixed boundary conditions (MBCs) using first order shear deformation theory (FOSDT) is studied. The governing equations of FGM cylindrical shells (FGMCs) are displayed according to the Donnell type shell theory and solved using the Galerkin's method. The novelty in this study is to obtain closed-form solutions of the eigen-value problem in mixed boundary conditions within the framework of the FOSDT. Finally, the effects of different volume fractions, FG profiles and shell characteristics on the critical parameters of FGMCSs with MBCs are studied in detail.

ABSTRACT: Understanding the characteristics of internal and external pressures on structures is important for structural design. This paper has experimentally observed internal and external pressures on long-span domes and investigated their non-Gaussian characteristics. Wind tunnel tests on internal and external pressure measurements for a single dome and two neighboring domes were performed. The distribution, non-Gaussian characteristics, and non-Gaussian peak factor of the internal and external wind pressure on the single dome were analyzed. After the results were validated, the distribution, non-Gaussian characteristics, and non-Gaussian peak factor of the internal and external wind pressure on the two neighboring domes under different wind attack angles (interference effect) were discussed. The results show that the characteristics of internal pressures on the single dome and the two neighboring domes are different from that of external pressures, and both the internal and external pressure show remarkable non-Gaussian characteristics. According to these characteristics, positive and negative areas of the internal and external pressure on the domes were defined, and the non-Gaussian peak factors were determined. This study has not only advanced our understanding on characteristics of internal and external pressure on long-span domes, but determined non-Gaussian peak factors that are used for structural design.

ABSTRACT: This study presents a new fiber reinforced polymer tube/filling strengthening method (i.e., FRP tube/filling strengthening) that creates a new composite compression member with a novel mechanical behavior, “bilinear behavior.” Previous experimental and theoretical studies have been conducted based on the ultimate state of the section. To thoroughly study the stiffness and entire loading process of this novel member, finite element analysis (FEA) models are built in this paper. First, the model development process considers the initial deflections and interface properties, and these models are verified by the experimental results. Two models of typical load-axial displacement curves describe the experimental results: a Bilinear model and a Trilinear model. Second, finite element modeling (FEM) is used to conduct a parametrical analysis that considers 7 parameters, and the results identify the mechanism of the strengthened member. Specifically, the Bilinear model corresponds to an unreinforced or relatively weakly reinforced specimen, and the Trilinear model corresponds to a relatively strongly reinforced specimen. If the exterior restraint system is weak, then the core steel buckles and subsequently yields; this behavior is described by the Bilinear model. If the exterior restraint system is strong (e.g., the length or the bending stiffness of the exterior restraint system is great), then the specimen can continue to bear a higher force after steel yielding until elastic-plastic buckling occurs; this behavior is described by the Trilinear model. Third, the FEA results and previous experimental and theoretical studies are used to obtain the stiffness and load-axial displacement curves, which are helpful for the design process. In general, relatively accurate FEA models are built in this paper that are capable of describing the mechanical behaviors of the novel member.

ABSTRACT: This paper presents experimental and numerical study on the behaviour of ultra-high strength steel (UHSS) hollow tubes under low velocity lateral impact loading. A total of six specimens were tested under lateral impact loading. The finite element (FÉ) model was established with the consideration of the strain rate effect and validated against test results. The parametric study showed that UHSS hollow tubes had the similar failure pattern when compared to that of normal strength steel members. The mid-span deflection and the residual deformation decreased significantly when the UHSS tube was applied.

ABSTRACT: In this article, a variational numerical method is utilized to investigate the nonlinear free vibrations of magneto-electro-elastic (MEE) plates under thermal environment. To this end, first, the basic equations are written based on the first-order shear deformation theory and von Kármán's geometric nonlinearity. Next, the constitutive equations are represented in matrix form. In the context of Hamilton's principle, the quadratic and matricized form of energy functional is derived which is then directly discretized on space domain by a method called Variational Differential Quadrature (VDQ). Periodic time differential operators are also constructed for discretizing on time domain. The final solution is obtained by the pseudo arc-length continuation algorithm. The effects of applied electric voltage, applied magnetic potential, temperature change and geometrical parameters on the response curves of MEE plates with different types of boundary conditions are studied.

ABSTRACT: This paper studies a nonlinear primary resonance of spiral stiffened functionally graded (SSFG) cylindrical shell with viscous damping force. The cylindrical shell is subjected to the harmonic excitation. The material properties of the shell and stiffeners are assumed to be continuously graded in the thickness direction. The FG cylindrical shell with internal and external spiral stiffeners is investigated. The strain-displacement relations are obtained based on the von Kármán nonlinear equations and the classical plate theory of shells. The
smeared stiffener technique is used to model the under-studied SSFG cylindrical shell. The obtained partial differential equations of motion are discretized by means of the Galerkin method. In order to find the nonlinear primary resonance, the multiple scales method is adopted. The effects of various geometrical characteristics and material parameters on the nonlinear primary resonance response of spiral stiffened simply supported FG cylindrical shells are investigated.

ABSTRACT: The third-order shear deformation theory (TSDT) effects on the thick functionally graded material (FGM) plates with fully homogeneous equation under thermal vibration are investigated by using the generalized differential quadrature (GDQ) method. The nonlinear coefficient c1 term of displacement field of TSDT is used to derive the equations of motion for thermal vibration of thick FGM plates. The dynamic equilibrium differential equations with TSDT of FGM plates in terms of partial derivatives of displacements and shear rotations subjected to partial derivatives of thermal loads, mechanical loads and inertia terms are derived in matrix forms. Three parametric effects of varied-modified shear correction factor, environment temperature and FGM power law index on the thermal stress and center deflection of FGM thick plates with and without containing the nonlinear coefficient c1 term are investigated.

ABSTRACT: In this work, an appraisal of the influence of the residual stresses and geometric imperfections is carried out for thin-walled I-shaped sections covering both hot-rolled and welded profiles based on a numerical study using the Finite Element Method. The Eurocode 3 design provisions for local buckling are presented and evaluated in comparison to the numerical results. Several residual stress patterns and geometric imperfection’s amplitude and shape are considered to determine their effect on the ultimate strength of the cross-sections. Additionally, it is described a procedure to assess the flange and web interaction under different imperfection assumptions, and its influence investigated. The conclusions from this study are that the Eurocode 3 design provisions for hot-rolled sections are appropriate, but should be further improved for welded sections, mainly because the influence of the welded residual stresses is detrimental for the cross-section capacity and its effect is not to accounted for adequately. Finally, this study provides relevant information for the numerical modelling of thin-walled I-shaped sections concerning the consideration of geometrical imperfections and residual stresses.

ABSTRACT: This paper presents experimental and numerical studies on the effect of multi-stitching pattern on the energy absorption capability of composite tubular structures under impact loading. A new multi-stitching pattern was developed to study the increase of specific energy absorption capabilities in GFRP and CFRP crash absorbers. The stitching pattern on both specimens showed a significant increase in energy absorption capability under impact loading. According to our results, the specific energy absorption of GFRP and CFRP composite tubes are 17% and 18% higher than non-stitched specimens respectively. A multi-shell finite element model was constructed to predict the axial crushing behaviour and energy absorption capability of composite structures under impact loading. The method is based on an energy-based contact card modelling technique in the stitched and non-stitched area, and the initiation of main central crack growth occurs when the critical separation (PARAM function) is attained, and this represents the functionality of the stitched area during an impact event. The developed numerical approach is efficient in terms of accuracy and simplicity in comparison with the existing methods for multi-layered composites structures.

ABSTRACT: Increasing the development in industrial technology and need for energy absorption, lightweight and cost effective composite materials such as composite sandwich panels have been in the center of attention. In this paper energy absorption properties of proposed composite sandwich panels with different corrugated core geometries under quasi static out of plane loading conditions is experimentally investigated. Three different corrugated shapes, i.e. rectangular, trapezoidal and triangular fabricated with the same thickness are used. The specimens were subjected to three different quasi-static compression loading condition i.e. concentrated, linear and planar. The effect of the number of unit cells and corrugated core geometries in determining the overall deformation and local collapse behavior of the panels also investigated. Based on the comparative results, it is found that three unit cell rectangular corrugated geometry possessed the best performance than other types of corrugated core geometries. Moreover, through visual observation the damage mechanisms under loading conditions and subsequent failure modes are inspected. Plastic buckling of cell walls and foam densification identified as the initial failure modes and by continuing the loading, fiber breakage, localized delamination as well as debonding between the skins and the core were the main damage mechanisms in these corrugated systems.

ABSTRACT: In engineering, the bending deformations of thin-walled tubes mostly are under three-point loading. However, for the dual rectangle thin-walled tube (DRTWT), the theoretical prediction of the three-point bending collapse is still an unsolved problem. In this paper, the three-point bending collapse of the DRTWT is innovatively investigated using theoretical prediction and experimental verification. The global energy equilibrium theory is applied to derive the bending characteristic of the DRTWT. It is assumed that all the bending energy is absorbed and distributed along the hinge lines and in the toroidal surfaces during the bending collapse. The analytical results show good agreement with the experimental results. Finally, a simplified bumper structure of automobile is created by using beam elements and spring elements with the derived bending characteristics, which can effectively replace the detailed finite element model (FEM) to accelerate the crashworthiness design of automotive structure at the conceptual design stage.

ABSTRACT: Concrete-filled steel tubular (CFST) structures are extensively used in engineering applications in China owing to their high strength and section modulus, ease of construction, and good seismic performance. However, the steel tubes of CFST members are prone to outward buckling under compression loads. Welding longitudinal stiffeners on these steel tubes is one of the most efficient approaches used for delaying the local buckling and improving the mechanical performance of CFST members. This study attempted to investigate the eccentric compression behaviour of concrete-filled stiffened steel tubular members with square sections by experimental studies and finite element analysis (FEA). First, 12 CFST columns with different slenderness ratios and loading eccentricities were subjected to compression loads and tested. It was found that the use of stiffeners increased the ultimate strength and improved the stability of the columns. Subsequently, the behaviour of the stiffened CFST columns was investigated by performing a three-dimensional FEA. The accuracy of the FEA model was verified based on the test results. The working mechanisms of the stiffened CFST members were analysed in detail in terms of the failure modes, load versus deformation responses, deformation of the steel tubes, interaction between the steel tube and core concrete, as well as axial stress distribution of the core concrete. A parametric study was conducted to further evaluate the stiffening schemes that affected the ultimate strength and ductility of the CFST members. Finally, design recommendations on the type of eccentrically-loaded stiffened CFST columns were provided.
ABSTRACT: The low-velocity impact response of sandwich beams with aluminum alloy face-sheets and three core configurations (i.e., the positive layered-gradient core, negative layered-gradient core and non-gradient monolithic core) was first investigated by using a drop-weight machine. The impact bending tests were performed on specimens at five impact energy levels – 9.80 J, 22.05 J, 39.19 J, 61.24 J and 88.18 J – by varying the drop height of the weight. Based on experimental results, the corresponding numerical simulations and a multi-objective design optimization were performed. The experimental results show that all sandwich beams fail via the global bending deformation without local crack/fracture under lower initial impact energy, while they fail via larger bending deformation accompanied by obvious core tensile crack at mid-span and core shear at clamped ends with the increased initial impact energy. The resistance of both gradient core sandwich beams to impact flexure loading is weaker than that of non-gradient monolithic core sandwich beams. Simulation results indicate that the ratio of energy absorbed by core decreases with the increased impact energy, while the ratio of energy absorbed by face-sheets increases with the increased impact energy. The boundary condition is demonstrated to have great influence on the force-displacement response for all sandwich beams. Finally, the corresponding Pareto fronts representing a group of best trade-off designs were obtained.

ABSTRACT: Elevated cylindrical metal silos are often supported on a ring beam which rests on discrete column supports. The ring beam plays an important role in redistributing the majority of the discrete forces from the column supports into a more uniform stress state in the cylindrical wall, which is necessary to reduce the potential for buckling of the shell wall. Traditional design treatments assumed that the discrete support forces can be fully redistributed by the ring beam, producing circumferentially uniform axial membrane stresses in the silo shell. But it has previously been shown that only a very stiff ring beam can produce even relatively uniform axial membrane stresses in the shell. The ring beam stiffness must be evaluated relative to the stiffness of the silo shell in compatible deformation, since even a thin shell is extremely stiff in its own plane. A test for the ring beam to shell stiffness ratio was previously devised by the authors to determine the ring beam stiffness needed to achieve uniform membrane stresses. This new study assesses ring beams of practical dimensions and stiffness, to evaluate their effectiveness in smoothing the shell axial membrane stresses towards the uniform condition and then to find their effect on the buckling resistance of the shell. This study explores the stress resultants in a closed section ring beam of practical dimensions that is less stiff than the ideal stiffness using a finite element parametric study of the flexible ring beam and connected silo shell. The results show that the ring beam stress resultants, relative to those in an isolated ring beam under the same loading, can be directly related to the established shell to ring beam stiffness ratio (ψ). This treatment may be used to significantly enhance current design practice which, according to the Eurocode EN 1993-4-1 for silos, assumes that the shell applies the full uniform transverse loading onto an isolated ring beam.

ABSTRACT: Aluminium alloys have high strength-to-weight ratios and great durability; thus, they have been extensively used in structural applications. Channel sections have a smooth and aesthetically pleasing line shape, good integrity, and are easy to connect. An experimental program using 28 specimens and a numerical study that generated 100 results were conducted on aluminium alloy columns of plain and lipped channel sections. The nominal length of columns ranged from 300 mm to 3000 mm. The generated 128 results were evaluated with respect to the existing design specifications from America, Australia/New Zealand, Europe and China. Furthermore, the direct strength method (DSM) and the continuous strength method (CSM) were also used to predict results for comparison. The results showed that the design specifications produced conservative compression strengths of aluminium alloy columns of both plain and lipped channel sections. The CSM
provided more accurate and consistent design strengths. In addition, the reliability levels of the four international design codes, DSM and CSM for channel sections of aluminium alloy columns were also evaluated.

ABSTRACT: Free vibration of ultralight all-metallic (Ti-6Al-4V alloy) sandwich beams with corrugated channel cores was investigated by experiments and finite element (FE) simulations. The natural frequencies and mode shapes were measured and compared with simulations from both three-dimensional model (3D model) and two-dimensional equivalent model (2D model). Predictions of the 2D model agreed well with results obtained from the 3D model and experiments. It was found that for sandwich beams, the topological change from corrugated core to corrugated channel core eliminates the anisotropy of the structural stiffness and suppresses the local modes of vibration. The effect of geometrical parameters on the first natural frequency was also explored. In addition, preliminary assessment of the influence induced by varying the core topology was carried out. The first natural frequency of sandwich beams with corrugated channel cores having an inclination angle $\theta > 45^\circ$ is higher than those of sandwich beams constructed with competing core topologies, including tetrahedral, Kagome and pyramidal trusses and hexagonal honeycombs.

ABSTRACT: Based on the Simplified Super Folding Element (SSFE) theory, the theoretical prediction of average crushing force ($F_{\text{avg}}$) for multi-cell thin-walled structures is inferred and a combined five-cell thin-walled structure used in high speed train is proposed and investigated in this paper. The finite element model of the proposed structure and the theoretical prediction are validated by a full scaled impact experiment. Then, parametric studies are performed to evaluate the effects of design variables, including the thickness ($t$) and the side length ($a$) of the orthohexagonal cell, on collision responses based on the validated FE model and theoretical prediction. It is found that both specific energy absorption (SEA) and the maximum initial force ($F_{\text{max}}$) are obviously affected by the design parameters. Particularly, the effect of parameter $t$ on crushing performance is greater than that of parameter $a$. In further, to minimize the $F_{\text{max}}$ and maximum SEA under the constraint of $F_{\text{max}}$, a multi-objective robust optimization methodology is adopted. The Optimal Latin Hypercube Design (OLHD) and orthogonal design are combined to perform Design of Experiment (DoE) and dual response surface models (DRSM) are constructed for the optimization. The optimal results of deterministic optimization indicate that the $F_{\text{max}}$ decreases by 11.07% compared with the original design while the robust optimization optimal result of $F_{\text{max}}$ decreases by 10.01%. However, the robust optimization optimal design is more acceptable considering the robustness, which means the robust optimization is more attractive than deterministic optimization in practical engineering application.

ABSTRACT: This paper describes a numerical study on the section moment capacity of a doubly symmetric hollow flange steel plate girder (HFSPG) for use in long span applications. The HFSPG is manufactured by welding industrially available cold-formed rectangular hollow sections to a steel web plate. Suitable finite element models were developed first to simulate the section moment capacity tests conducted on the proposed HFSPGs using a four-point bending test arrangement. The experimental conditions in terms of boundary conditions, lateral restraints, mechanical properties, initial geometric imperfections and residual stresses were modelled carefully. The comparison of ultimate moment capacities, moment versus deflection plots and failure modes proved the validity of the developed finite element models to investigate the section moment capacities of HFSPGs. However, the slenderness of the tested HFSPGs was limited to the inelastic region. Hence the validated finite element models were used in a detailed parametric study to extend the results to a wider
slenderness range. The parametric study results of the section moment capacities were compared with the predictions of the relevant Australian, American and European hot-rolled and cold-formed steel design standards and suitable recommendations were made in relation to their accuracy in predicting the capacities of compact, non-compact and slender HFSPGs. Finally this paper proposes a new Direct Strength Method based design for HFSPGs.

ABSTRACT: This paper proposes a new circumferentially corrugated square tube (CCST) with a cosine profile. The cross section of the CCST is controlled by a cosine expression with parameters that include the number (N) of cosine wave crests, the amplitude (A) and the nominal side length (2L). Finite element (FE) models validated by experimental results were constructed in LS_dyna to analyse the crashworthiness performance of the CCSTs. The numerical results show that the collapse modes of CCSTs are classified into five types, i.e., non-ordered progressive mode (NPM), ordered progressive mode (OPM), inversion mode (IM), global buckling mode (GBM) and extensional mode (EM). After analysing the collapse characteristics, force-displacement characteristics and crashworthiness indexes, we found that the OPM has better crashworthiness performance than the other modes. Moreover, a more comprehensive parametric study was conducted to understand the effects of the geometric parameters N, A and wall thickness (t) on the crashworthiness performance of CCSTs. The results show that the collapse modes of CCSTs are fairly sensitive to the cross-sectional configuration and wall thickness. Increases in N, A and t all cause increases in the initial peak crushing force (IPCF), and the wall thickness t has the most significant effect on IPCF. However, the effects of the three geometric parameters on specific energy absorption (SEA) are much more complicated and are largely dependent on whether the collapse modes change or not with increases in the three parameters. The numerical results also show that the SEA of CCSTs is improved by 51.62% compared with that of a square tube (ST) when they have the same mass (55.3 g) and by 69.24% when they have the same wall thickness (t=1.25 mm). These results reveal that CCSTs with OPM have good energy absorption ability.

ABSTRACT: The paper deals with buckling of metal cylindrical silos composed of corrugated sheets and thin-walled open-sectional columns. A simplified silo wall segment model with a few columns was proposed for calculations of the global buckling strength of silos instead of comprehensive 3D computations of the entire silo structure. Calculations were carried out for three real silos with a different geometry (two slender silos and one intermediate slender silo). Comprehensive linear bifurcation/buckling analyses and geometrically non-linear stability analyses for both imperfect and perfect silos were applied. Silos and silo wall segments were mainly modelled both with an equivalent orthotropic shell for walls and 1D beam elements for thin-walled columns and with shell elements for walls and columns. The silo walls were loaded by tangential wall pressure, horizontal wall pressure and patch load according to Eurocode 1. The simplified silo wall segment models fully proved their efficiency in FE calculations of the buckling strength of silos.

ABSTRACT: Cold formed steel sections are normally produced by cold work manufacturing processes. The amount of cold work to form the sections may induce residual stresses in the section, especially in the area of bending. Studies by previous researchers of the effects of local buckling on the failure mechanics of thin-walled compression members have shown that ultimate failure will occur when the yielding has reached most of the middle surface in the corner region of the sections. Hence, these cold work processes may have significant effects on the section behaviour and load-bearing capacity. Most of the studies have investigated the effect of residual stresses raised from roll-forming operation and its influence on steel section behaviour. However,
press-braking has not received much attention. Therefore, a 3D finite element simulation has been employed to simulate this forming process. This study investigated the magnitude and distribution of residual stresses along the length of the corner region and through thickness residual stress variations induced by the press-braking forming process. The study concluded that residual stresses are not linear longitudinally (along the corner region). Maximum residual stresses exist near the middle surface of the plate. The neutral surface contains a combination of compressive and tensile residual stresses. The neutral axis is shifted from mid-surface by 7.5% of the plate thickness due to bending. The comparison of the 3D-FE results with the existence of 2D-FE results illustrates that the 3D-FE results show a variation in the transverse and longitudinal residual stresses along the plate length.

ABSTRACT: Circular holes can be commonly found in the web of cold-formed steel beams to accommodate services such as electric wires and pipelines. The presence of holes will reduce the critical buckling stress of the beams. Hancock proposed solution for determining the distortional critical stress of channel section beams, but limited to the sections without holes. This paper presents an analytical study on the distortional buckling of cold-formed steel channel-section beams with circular holes in the web. Hancock’s solution has been modified to derive a simple formulation for approximating the elastic critical stress and moment of distortional buckling of the channel-section beams with circular holes in the web, which are compared with those from the finite element buckling analysis using ANSYS. Finally, the influence of multiple holes on the distortional buckling behaviour and corresponding elastic buckling stress of beams in bending is discussed.

ABSTRACT: As a first endeavor, the nonlinear bending behavior of functionally graded carbon nanotube reinforced composite (FG-CNTRC) annular plates with variable thickness on an elastic foundation is scrutinized in this research. The nonlinear governing equations are established according to the third-order shear deformation theory (TSDT) in conjunction with the nonlinear von Karman strain field. A Pasternak elastic foundation is assumed to be in contact with the annular plate during deformation. To discretize the nonlinear governing equations and boundary conditions, the generalized differential quadrature method (GDQM) is adopted and the nonlinear system of equations is solved via the Newton-Raphson iterative method. Through the numerical results, effects of the elastic foundation, geometrical parameters, boundary conditions, CNT dispersion and volume fraction, thickness-to-radius ratio and thickness profile are investigated in detail. It is shown that CNT volume fraction and dispersion have a remarkable effect on improving bending behavior of the annular plate. It is found that thickness profile plays an essential role in the bending response of the annular plate.

ABSTRACT: A solution of the vibration problem for a composite orthotropic cylindrical shell with rigid weightless disks attached to its ends is presented in the paper. Using the Ritz method, the frequencies of the axisymmetric vibrations of the shell are determined. The clamped-clamped beam functions and their third derivatives are adopted as approximating functions for the shell deflection and axial displacement. Such an approximation satisfies the boundary conditions, according to which the shell deflections, angles of rotation, and axial reactive forces exerted on the end disks are zero. Based on this solution an analytical formula is derived for the calculations of the frequencies of axisymmetric vibrations. Using this formula, the vibration frequencies have been calculated for composite orthotropic shells with different lengths. The results were successfully verified by the finite element analyses. The effect of the fibre orientation on the vibration frequencies of the shell made of unidirectional carbon fibre reinforced plastic is investigated. Based on this analysis, the angles of the reinforcement orientation delivering the maximum and minimum values of the
frequencies are determined. It is found that irrespective of the shell length, the high mode frequencies reach their maximum values for the shells reinforced in the hoop direction.

ABSTRACT: In the present work, nonlinear dynamics of fluid-conveying functionally graded material (FGM) sandwich nanoshells is investigated. In order to describe the large-amplitude motion, the von Kármán nonlinear geometrical relations are taken into account. Compressibility and viscosity of the fluid are neglected, and the velocity potential and Bernoulli's equation are used to describe the fluid pressure acting on the nanoshells. Based on the classical shell theory and incorporating the surface stress effect, the governing equations are derived by using Hamilton's principle. After that, the Galerkin method is used to discretize the equation of motion, resulting in a set of ordinary differential equations with respect to time. The ordinary differential equations are solved analytically by utilizing the method of multiple scales. Results show that the surface stress plays important roles on the nonlinear vibration characteristics of fluid-conveying FGM sandwich thin-walled nanoshells. Furthermore, the fluid speed, the power-law index, the fluid mass density, the core thickness and the initial surface tension can also influence the vibration characteristics of fluid-conveying FGM sandwich nanoshells.

ABSTRACT: Temporary structures, which are designed to be quickly erected and in service for short periods of time, are widely used in performances and sports competitions. This temporary characteristic requires special construction to be implemented. This paper presents a new modular support structure that can be used as temporary grandstands, stages, ski runs and disaster relief rooms. This modular support structure is composed of the foldable plane frame with corresponding joints. The assembly property is achieved through joint connection among these frames. The local folding characteristic of these plane frames improves both erection and transportation efficiency. As a core component of this modular support structure, the aluminum alloy assembly column was particularly concerned and the axial stability of the column was investigated experimentally. The results indicated that the use of the connection ring could improve the stability of the assembly column along with the connections between the foldable plane frames. Numerical analysis of the tested specimens under axial compression was developed. The ultimate strength, failure modes and load-displacement curves obtained from the numerical results agreed well with the test results. Equivalent stability factors of the assembly columns were calculated to further illustrate axial stability of the column.

ABSTRACT: This paper presents the buckling and postbuckling behaviors of graphene-reinforced composite (GRC) laminated cylindrical shells subjected to torsion in thermal environments. The GRC layers of the shell are arranged in a piece-wise functionally graded (FG) distribution pattern in the thickness direction and each layer of the shell contains different volume fraction of graphene reinforcement. The extended Halpin-Tsai micromechanical model is employed to determine the temperature dependent material properties of GRC layers. The governing equations of the GRC laminated cylindrical shells under torsion are derived based on a higher-order shear deformation shell theory with the geometric nonlinearity being defined by the von Kármán strain-displacement relationship. A singular perturbation technique along with a two-step perturbation approach is employed to determine the buckling torques and the torsional postbuckling equilibrium paths of the FG-GRC laminated cylindrical shells in thermal environments. The numerical results obtained reveal that the piece-wise FG distribution of graphene volume fraction can enhance the buckling torque and the torsional postbuckling strength while the rise of temperature may lead to the reduction of the torsional buckling torques and torsional postbuckling strength of the GRC laminated cylindrical shell.

ABSTRACT: Tensegrity systems have the potential of offering a high level of structural efficiency and result in lightweight reconfigurable structures. However, there is few actual application of the tensegrity concept in engineering practice, which can be mainly attributed to the inadequate knowledge concerning the mechanical behavior of these systems. Although, most of the performed instability analyses on tensegrity systems to date concern with progressive collapse under static loads, so far no investigation has been conducted on the dynamic instability of these systems. In this paper, two geometrically rigid configurations assembled from half-cuboctahedron (HC) modules and crystal-cell pyramid (CP) modules under impulsive loads are analyzed, for demonstration purposes, with the intention of comparing critical dynamic loads to critical static loads. Also, other parameters, considered in this work, include the impulsive time duration, self-stress level, struts slenderness ratios, damping ratios, support conditions, and struts strengthening. It is found that in the investigated cases, as the time durations are reduced, being less than quarter of the first natural frequency, the critical load ratios increase and the systems are able to withstand dynamic loads that are substantially in excess of the critical static loads. Decreasing self-stress level by 40% in the studied HC configuration can significantly increase the amount of relative dynamic to static load ratio up to 193%, 177% and 170% under rectangular, triangular and half-wave sine loadings with time duration of 0.05 s, respectively. The increase in critical impulsive load capacity of the studied CP configuration is typically less than 10% for the same reduction of the self-stress level. There is a significant increase in dynamic loads attaining approximately 20% for an increase of 24% in cross-section of critical struts in the studied HC configuration.

ABSTRACT: In the proposed buckling-restrained brace (BRB), a concrete infilled glass-fibre reinforced polymer (GFRP) tube is used instead of a conventional concrete infilled steel tube to restrict steel inner core buckling. It has the following advantages: 1) The GFRP is a high-strength and flexible material available for structural components; 2) Its use as an outer constraint material is also a solution for poor corrosion resistance of the outer steel tube; In this study, 11 BRB specimens with concrete infilled GFRP tubes and 3 BRB specimens with concrete infilled steel tubes were designed to investigate the effects of the types of GFRP and constraint ratios on the hysteretic behaviour of the GFRP tube BRBs. The performance of the GFRP tube BRBs was also compared to the steel tube BRBs composed of three different lengths of steel tubes with the same wall thickness. All the GFRP tube BRB specimens had the same rectangular steel inner core and included two types of GFRP tubes with three different lengths and thicknesses. The medium- and long-length filaments winding GFRP tube BRB specimens buckled at the last stage of the test, while global buckling developed the cracks in the middle of the GFRP tube. All other BRB specimens didn’t buckle and underwent the complete loading process without degradation in stiffness and strength. The finite element models of BRBs were built using ABAQUS, considering the constitutive models of the GFRP, steel and concrete subjected to cyclic loading. The finite element model of the GFRP tube BRBs could simulate the performance of the BRBs well, and the results of analysis were calibrated with experimental results. All the BRB specimens exhibited good hysteretic behaviour, sufficient load-bearing capacity, large ductility and energy dissipation capacity. The GFRP tube BRBs may share the same design criteria as the traditional steel tube BRB by limiting their constraint ratios, and the GFRP tube may be used as an alternative to the traditional outer restraining tube especially for those BRBs with strict durability requirement.

ABSTRACT: In this paper, the ability of the active thermography as a non-destructive testing technique to detect internal damages in circular cylindrical shells is investigated. The transient heat transfer problem of the damaged structure is analyzed using the ABAQUS numerical modeling software. To reveal the defects more

ABSTRACT: This paper addresses an improved cross-section analysis approach for calculating the deformation modes of thin-walled cross-sections with circular rounded corners in the framework of generalized beam theory (GBT). The cross-section discretization, in contrast to the classic GBT one, the circular rounded corners are treated as independent circular walls, and deflection functions of the corresponding circular arches, which play the role of basis functions, are used to approximate the in-plane displacements of any points on the corner mid-line. Because the geometries of the circular corners are accurately modelled by curved elements, the proposed procedure is more efficient than those based on the polygonal approximation of the corner mid-lines. Illustrative cases concerning the employment of the procedure to four cold-formed cross-sections are presented to show its validity and potential. Through comparisons of the proposed procedure against that based on the polygonal approximation, it is shown that it yields accurate results with much coarser cross-section discretization.

ABSTRACT: The paper investigates the effects of the geometrical imperfections in buckling analyses of plated steel elements at elevated temperatures and provides an alternative branch-switching procedure to perform post-buckling analyses without introducing initial imperfections into the model. This procedure is appealing since the choice of appropriate imperfections in classical analyses is not straightforward, above all at elevated temperature. Several numerical analyses show that the choice of the imperfections is not trivial and that the buckling mode may vary with temperature. They also show that the proposed branch-switching procedure is an interesting preliminary tool to understand the instability behaviour of steel structural members.

ABSTRACT: This paper is focused on the stability of polymer disks subjected to uniform radial edge compression and proposes a methodology to determine the critical pressure at the onset of buckling. The methodology involves the design and fabrication of a tooling system to compress the outer disk surfaces and move material inward in order to apply a uniform radial pressure in the free (unconstrained) volume of the disks. The main objective is to circumvent the application of classical analytical solutions to polymers that exhibit a decrease of the stress-strain curve and negative values of the tangent modulus after initial yielding through determination of the critical pressure at the onset of buckling by matching the experimental and finite element predicted evolutions of the force vs. displacement. A lower bound stress solution is provided to perform a simple and fast conversion of the experimental data into the critical pressure of the polymer disk at the onset of buckling. The results of this investigation can be successfully applied to characterize the forming conditions that give rise to out-of-plane buckling deformation of the polymer centre during the production of a new generation of polymer-metal coins.

ABSTRACT: This study examined the buckling of spherical caps fabricated under different conditions of wall-thickness reduction. The spherical caps were fabricated using photosensitive resin and had a base diameter of 150 mm and height of 41.1 mm; they were subjected to uniform external pressure. In total, 42 spherical caps—6 with full thickness reduction and 36 with partial thickness reduction—were fabricated through rapid
prototyping; after their external surface and wall thickness were measured, all caps were tested to collapse to experimentally and numerically evaluate their buckling properties, namely buckling pressures and collapse modes. Moreover, the effects of site, magnitude, and range of the thickness reduction on the buckling properties were evaluated. Herein, the experimental and numerical results are comparatively presented in tables and figures.

ABSTRACT: A semi analytical method is employed to analyze free vibration behaviors of composite laminated cylindrical and spherical shells subject to complex boundary conditions. The analytical model is established on the basis of multi-segment partitioning strategy and first-order shear deformation theory. The displacement functions are made up of the Jacobi polynomials along axial direction and Fourier series along circumferential direction. In order to obtain continuity conditions and satisfy complex boundary conditions, the penalty method about spring technique is adopted. The solutions about free vibration behaviors of composite laminated cylindrical and spherical shells were obtained by approach of Rayleigh–Ritz. The convergence study and numerical verifications for composite laminated cylindrical and spherical shells with different boundary conditions, Jacobi parameters, spring parameters and truncation of permissible displacement functions are carried out. Through the comparison and analysis study, it is obvious that the proposed method has a good stable and rapid convergence property and the results of this paper closely agreed with those obtained by published literatures, FEM and experiment. In addition, some interesting results about free vibration characteristics of composite laminated cylindrical and spherical shells are investigated.

ABSTRACT: This paper focuses on the stability of steel columns with cruciform section under uniform compressive and shear stresses. The complex finite strip method (CFSM) is employed to solve the buckling of open thin-walled steel columns. CFSM results are validated against other numerical techniques. CFSM has high convergence, accuracy and superior computational efficiency. Due to the use of complex functions, it can also capture shear buckling. The influence of longitudinal stiffeners and section geometry on the buckling behavior of stiffened cruciform sections is investigated. The buckling behavior of cruciform sections is compared against U, I, and T section steel columns.

ABSTRACT: In this paper, the optimum positions of multiple (two) longitudinal stiffeners for steel plates subjected to pure bending, and combined bending and shear forces, are investigated by using the gradient-based interior point optimization algorithm. An eigenvalue analysis is performed by means of the finite element method, and an optimization algorithm is employed to maximize the buckling coefficients until attaining the optimum position of the stiffeners under various loading conditions. In order to ensure the accuracy of the method, the results obtained from this research are compared with analogous results found in the literature. Based on this study, the optimal location of a single and two longitudinal stiffeners are recommended for plates under pure bending. In addition, the interaction curves between the optimum stiffener location and bending-shear ratio for plates subjected to combined bending and shear forces are proposed for practical design.

ABSTRACT: In this study, for the first time, we present a shell finite element based on positions and generalized vectors for instability analysis of thin-walled members. The presence of generalized vectors and
transverse strain enhancement guarantee to the proposed formulation a good representation of strain and stress fields inside the element, allowing the use of complete three-dimensional constitutive law without any locking. The proposed formulation is total Lagrangian and naturally covers large displacement modeling. In past studies, the presence of generalized vectors limited the connection of shell portions or non-tangential panels, making it difficult to model thin-walled members. To solve this problem, a strategy to ensure the connection between non-coplanar elements, considering the stiffness of the connecting material, is originally developed and presented in this paper. In numerical examples we explore differences among buckling load achieved using small displacements and first limit points (or bifurcation points) using large displacements. The influence and the sensitivity of the connection stiffness are also tested when comparing these values. Results are validated against literature reference values and new examples are proposed to show the applicability of the positional formulation.

ABSTRACT: Natural frequencies of circular deep arches made of functionally graded materials (FGMs) with general boundary conditions are obtained in this research based on the unconstrained higher-order shear deformation theory taking into account the depth change, complete effects of shear deformation, and rotary inertia. The material properties are assumed to vary continuously through the thickness direction of the arch. Displacement field within the arch is obtained through expansion up to an arbitrary order. Governing differential equations of the in-plane vibration are derived using Hamilton's principle. These equations are solved numerically utilizing the differential quadrature method (DQM) formulation. In order to illustrate the validity and accuracy of the presented results, results are compared with the available data in the open literature. Afterwards, novel numerical results are given for free vibration behaviour of the FGM deep arches with various boundary conditions.

ABSTRACT: This paper describes a numerical investigation into distortional-global buckling interaction of cold-formed steel perforated rack uprights when subject to axial compression. The numerical modelling strategy is carefully validated against existing experimental data. The strengths and failure modes of perforated uprights obtained from finite element analysis are compared with design strengths predicted using the direct strength method (DSM). The comparisons indicate that the ultimate strengths predicted by the current DSM are unsafe for perforated rack uprights. Hence, modifications on the DSM formulae were proposed and are presented by considering the interaction of distortional and global buckling modes for perforated rack uprights.

ABSTRACT: Cold-formed steel (CFS) is an emerging construction material that has been gaining momentum over the past few years. While the behavior of structural members made of CFS has been extensively studied at ambient conditions, the performance of these members under extreme events such as that associated with fire, is yet to be understood. In order to bridge this knowledge gap, this paper presents outcome of numerical studies aimed at understanding fire response of CFS beams. More specifically, this study explores the effect of temperature-induced shear-based instability on response of C-shaped CFS beams with slotted webs. For studying this phenomenon, a three-dimensional nonlinear numerical model is developed using the finite element (FE) simulation environment; ANSYS. The developed FE model is designed to incorporate temperature-dependent material properties as well as to account for unique geometric features and restraint conditions, as to accurately trace thermal and structural response of CFS beams. Once validated, the developed model was utilized to examine the effect of a number of factors namely; channel depth, web perforation pattern, as well as boundary conditions, on temperature-induced buckling susceptibility of CFS beams. The obtained results
showed that these examined factors can significantly affect shear response of CFS channels with slotted webs at elevated temperatures. Findings observed from FE simulations were also shown to agree with that obtained from especially derived design expressions that give due consideration to geometric features and temperature-dependent material properties of slotted webs. This study concludes that in order to accurately capture the response of fire-exposed CFS beams, an accurate presentation of geometric and material features in such members is essential.

ABSTRACT: This paper presents an experimental study on concrete-filled steel tubular (CFST) beam-columns with square sections under combined sustained load and chloride corrosion. A total of 11 specimens (including 7 CFST members and 4 reference hollow steel tubes designed for comparison) were tested under 120-day sustained load in accelerated chloride corrosion environment and then loaded to failure. The main test parameters include load ratio (ratio between the long-term sustained load and the ultimate capacity of the specimen under short-term loading) and corrosion depth. The failure modes, full-range load-displacement relationship, load-strain relationship and ductility were measured and compared. Based on the experimental observation, mechanism of CFST beam-column members under the combined effects of sustained load and chloride corrosion was discussed and compared to the reference hollow steel tubes. Traditional design methods were modified for the consideration of combined sustained load and corrosion, which were calibrated and evaluated against the test results.

ABSTRACT: The present paper introduces two types of inner cellularization geometry in the thin-walled cylinders derived from previous studies on this area of subject. Novel geometries were proposed in this research. These configurations were the result of modifications to the previous works. Moreover, these absorbers were proposed to increase the specific energy absorption, reduce the peak energy, and improve crushing. The maximum Specific Energy Absorption (SEA), minimum Initial Peak Crushing Force (IPCF) under quasi-static axial compression test at the rate of 10 mm/min, and thickness and height parameters of the thin-walled cylinder and length of the inner square's sides were considered the design variables to achieve the optimal state. In the present work, two DOEs (design of experiment) were performed in Design-Expert in accordance with the given surfaces for both geometries of the thin-walled cylinder's inner cores. Subsequently, for further investigation, the experimental results were compared with those obtained from the finite element simulation in Abaqus, revealing the desirable accuracy of the results. Finally, by applying the equations derived from the proposed model to each of the responses and geometries, their optimal states were obtained using both the desirability approach in Design-Expert and the MOPSO method in MATLAB. Thickness had the highest impact on both configurations. Moreover, the optimal thickness for both configurations was 1.4 mm in the selected range. As regards the multi-objective function, the best inner square edge lengths for the C2R and S2R configurations were the central and upper limits, respectively. Finally, the cylinder heights for the C2R and S2R geometries were 174 and 153 mm, respectively.

ABSTRACT: Thin-walled circular cylindrical shells are used in many civil engineering applications. Any initial geometric imperfections and the type of applied load determine the buckling and the post buckling of cylindrical thin-walled shell structures. Fourteen thin-walled cylindrical shell models in two groups (labelled without CFRP and with CFRP) with different dent directions (H= horizontal, V= vertical and D= 45° diagonal direction) and dent depths (2t and 4t) subjected to external pressure were tested in the present research (t is the
thickness of the cylindrical shell). The results of testing under different theories and codes are compared. Moreover, the results are identified and investigated in the present experimental research.

ABSTRACT: Thin-walled energy absorbers are one of the common structures that are used in vehicle body for increasing the crashworthiness and consequently decreasing injuries. Investigated new type of thin-walled aluminum matrix and a thin-walled steel punch energy absorber structure has been investigated in this paper. Energy is absorbed as the matrix expansion followed by simultaneous matrix and punch folding. Present study proposes a sandwich panel based on expanding-folding absorber units to evaluate their crush mechanism. Parametric study has been done using finite element code LS-DYNA while experimental tests have been implemented to validate the FE model. The panels have been tested under three axial quasi-static loading conditions including a rigid half-cylinder and a rigid plate. Parametric study considers the punch angle, matrix thickness and punch thickness. The optimum structure based on energy absorption has then been used as a structural member in the sandwich panel until a panel with high specific energy absorption be introduced. Also it have been seen that all the curves for the expansion section can be estimated using polynomial second order functions, with a high accuracy.

ABSTRACT: This paper presents a comprehensive analysis of mathematical models for estimating the shear strength of trapezoidal-corrugated steel webs. The existing database of experimental data on trapezoidal corrugated steel web beams and girders is updated by adding more test results, yielding a total of 144 tests. The three-parameter model, previously developed by the authors based on Richards equation is reduced to a two-parameter improved version based on Hill equation. Both models were found to have, essentially, the same performance when compared against test results of the updated database. Based on the Akaike Information Criterion, the new model was retained. The performance of the improved and previously published models is reviewed and tested against the updated database of test results. It was found that the improved model performed better than the existing models in many aspects. An uncertainty analysis was performed on the proposed model considering both, geometric and material parameters as random variables. Bootstrapping and the Point Estimate Method (PEM) were employed to propagate uncertainty and construct confidence intervals for the normalized shear strength. It was found that, overall, the coefficient of variation of the normalized shear strength increases with the slenderness ratio.

ABSTRACT: Thin-walled stainless steel channels are becoming more widely used in the residential and commercial sectors because of their high corrosion resistance, especially in situations where low maintenance is required. However, there is a need also for web perforations for ease of installation of services; as a result such sections are susceptible to crippling in the web, particularly under concentrated loads applied near to the web perforations. This paper considers the use of perforated cold-formed ferritic stainless steel unlimped channels with restrained flanges subject to interior-one-flange and end-one-flange loadings, known as one-flange loadings. A total of 288 results are presented, comprising 18 laboratory and 270 numerical results. The numerical analysis in this paper uses nonlinear quasi-static finite element analysis with an implicit integration scheme. A comprehensive parametric study is described to determine web crippling strength reduction factors for different sizes of web perforations and cross-section dimensions. It is noted that no cold-formed stainless steel standard provides strength reduction factors for any one-flange loading. The strength reduction factors are
first compared to reduction factors previously recommended for lipped cold-formed stainless steel channels. It is found that these existing equations are unreliable and unconservative for unlipped channels by as much as 20%. From both laboratory and finite element results, web crippling design equations are proposed for perforated channels under one-flange loadings; the proposed equations are shown to be reliable when compared against laboratory and numerical results.

ABSTRACT: Steel-concrete-steel (SCS) sandwich shells, which are combined with steel plates, concrete core and shear connectors, are usually applied as protective structures in the civil engineering. In this paper, nine curved SCS sandwich shells subjected to concentrated load by a hemi-spherical head were tested to obtain the failure characteristic, ultimate strength and load–displacement response. The finite element (FE) models of curved SCS sandwich shells were also established by using LS-DYNA. The accuracies of the FE models were verified by comparing the load–displacement curves, local and global deformation between the experimental results and FE predictions. The factors influencing the ultimate strength and deformation behavior of curved SCS sandwich shells were analysed, including concrete core and steel plate thickness, top to bottom steel plate thickness ratio and spacing of shear connectors. Through experiments and numerical simulations, three failure modes could be summarized. It was also found that increasing concrete core and top steel plate thickness and reducing the spacing of shear connectors could increase yield strength and ultimate strength of curved SCS sandwich shell. The increase of concrete core and steel plate thickness also led to higher energy absorption capacity; whereas, the spacing of shear connectors showed little effect on energy absorption capacity.

ABSTRACT: In order to develop an efficient energy absorption structure for protecting equipment against impact and blast shock, this research proposes a fourfold-tube system (FT) consisting of four tubes. Its performance was analyzed experimentally (quasi-static test) and numerical simulation with FE (finite element) models. The deformation mode of the FT system was described in detail by simulation and experiment. With the collapse of the outer tube, the upper inner tubes were pushed towards both sides of the lower inner tube, then three inner tubes are side-by-side in the outer tube and all the tubes were collapsed simultaneously, therefore the stress transmits to the protected structure to be distributed more evenly. As a consequence, the protection capability of the nested tube system is improved by enhancing energy absorption capacity and the robustness of deformation mode. The performance of FT system was compared with that of the triple-tube system (TT) and single-tube system (ST), both the experimental result and simulation results show that the FT system can provide the most stable deformed mode and the highest energy absorption efficiency. For mild-steel nested tube systems, the energy absorbed by the FT system is larger than that of the TT system by 30%, so the defense ability of the FT system is better than the TT system. The deformation mode of the FT system under dynamic load tested experimentally, the results prove that the nested system can works as expected at high strain rates. Finally, the FT system was tested with two type of dynamic loading conditions, impact and blast shock. The results demonstrate that the FT system can provide the most efficient impact force reduction and blast mitigation in protecting the structures from damage under impact and shock wave from the explosion.

ABSTRACT: Bending of steel cylindrical shells is generally characterized by the interaction among ovalization, bifurcation, and material plasticity when the slenderness of the shell is relatively low. It is a nonlinear phenomenon, which is dictated by buckling-sensitivity of the shells to imperfections. The behavior of
ABSTRACT: This study aims to develop an analytical solution for the elastic buckling pressure and its corresponding equilibrium path of confined, thin-walled liners subjected to temperature variations. The admissible radial displacement function and the minimum potential energy of liners are employed to establish the equations of equilibrium. The steel liners are modelled with two-dimensional finite elements for both elastic and inelastic behaviors. The elastic buckling pressure and the equilibrium path from the computational model are in excellent agreement with the analytical predictions. The analytical solutions for elastic liners and the numerical results for inelastic liners with material and geometric nonlinearities compare well with their respective test results available in the literature. Parametric studies are performed in terms of temperature.
variation, out-of-roundness imperfection, non-uniform liner-pipe gap, pipe supporting medium flexibility, and steel liner yield strength.

ABSTRACT: This paper proposed an innovative composite folded thin shell structure consisting of concrete, expanded polystyrene foam (EPS), and glass-fiber reinforced polymer (GFRP) to improve the mechanical performance of the traditional concrete thin shell structure. This lightweight structure was investigated through a scaled model test to characterize the load bearing behavior. For comparison the corresponding concrete thin shell and the concrete folded shell were also undergone loading tests. The results demonstrate that the bearing capacity of the composite folded thin shell is 4.876 times that of the concrete thin shell and 1.219 time that of the concrete folded shell respectively. The typical failure mode of composite folded thin shells is the crush of the top concrete layer at the mid-span. The presence of the bottom GFRP face sheet and the EPS core can effectively slow down the appearance of initial cracks in the concrete layer. The destruction of the composite folded thin shell shows a good ductility characteristic when compared with other two shells.

Zhixin Huang and Xiong Zhang (Department of Mechanics, Huazhong University of Science and Technology, Wuhan 430074, Hubei, PR China), “Three-point bending of thin-walled rectangular section tubes with indentation mode”, Thin-Walled Structures, Vol. 137, pp 231-250, April 2019,

ABSTRACT: The local indentation and bending collapse are two typical energy dissipation mechanisms of thin-walled tubes under lateral impacts. These two mechanisms are always developed simultaneously for tubes under three-point bending, but there are still few studies concerned with this phenomenon. This paper addresses the indentation mode of thin-walled tubes under three-point bending. Quasi-static experimental tests are conducted first for square tubes with particular dimensions, and the nonlinear finite element code LS-DYNA is then used to simulate the tests. Parametrical studies are conducted to analyze the influence of geometrical parameters on deformed shapes and force response. Results show that the span, wall thickness and punch diameter have significant influence on the response of tubes, while the sectional width has a small influence. On the basis of the analysis of energy dissipation mechanisms, a theoretical model is proposed to predict the force response of thin-walled tubes. Ideal rigid perfectly-plastic material assumption and the dimensional analysis method are employed to help derive the force-displacement characteristics. Finally, the theoretical predictions are validated by experiments and simulation results of thin-walled rectangular tubes with a wide range of geometric parameters.

ABSTRACT: The present research is aimed at verifying design rules for cold-formed steel (CFS) members under axial compression when local-distortional buckling modes (LD) is achieved. Sets of experimental results previously available were applied to calibrate a shell finite element model addressed to survey the structural behavior of CFS lipped channels under LD bucking interaction. A large range of distortional-local slenderness ratio was considered in order to obtain numerical results of LD interaction including strong and weak interaction conditions. Based on both experimental and numerical results, the nature of LD interaction was assessed and the column strength variation was observed according with the representative slenderness variables, $\lambda_s$, $\lambda_w$ and $R_m$, respectively local and distortional slenderness factors and distortional-local slenderness ratio $\lambda_d/\lambda_s$. The column strength variation was established based on the Winter-type equation, conceived to cover the complete range of LD interaction. The proposed solution follows the direct strength method concept, is easy to apply and accurate enough for the structural design of lipped CFS columns. Additional research is under way to include other CFS types in the proposed design approach.

ABSTRACT: The paper investigates the possibility of bifurcation buckling from axisymmetrical equilibrium states of a heated circular plate with immovable edge. The plate is composed of a functionally graded material whose mechanical and physical properties are varied in the thickness direction according to the power law. Because of high compressive circumferential stresses that develop near the edge, the symmetrically deformed plate can buckle into asymmetric equilibrium configurations characterized by local circumferential waves (wrinkles). The problem of determining wrinkling thermal loads is formulated using the von Karman nonlinear plate theory based on the concept of physically neutral surface and solved by the power series method. The existence of wrinkling loads is examined for various pressure levels and boundary conditions. The calculation results are compared to the finite-element solution obtained by a general-purpose shell element.

ABSTRACT: Thin-walled structures are widely used in energy absorbing devices attributed to their light weight and excellent energy absorption efficiency. In this paper, an innovative sandwich sinusoidal lateral corrugated tubes (SSLCTs) was proposed. It consists of the outer circular tubes (OCTs), the inner circular tubes (ICTs) and a new type of lateral corrugated tubes (LCTs) with a sinusoidal cross-section in the middle. Systematic crashworthiness study for SSLCTs is carried out with multi-objective optimization design. The results show that the wall thickness of ICTs plays an important role in the specific energy absorption, while the wall thickness of OCTs plays a major role in initial peak force. The multi-objective optimizations of SSLCTs with \( N = 6 \) and \( N = 10 \) were performed. The optimization results show that the Pareto frontier coverage is wider for SSLCTs with \( N = 6 \) than \( N = 10 \). But these two different SSLCTs get almost identical optimal solutions. Finally, the interaction effects were also studied and it was found that the highest initial peak force was reduced by 22.39\%, and the specific energy absorption was increased by 16.75\% compared to the separate compression of individual tube.

ABSTRACT: Shear buckling resistance is one of the most important load cases to be considered when designing steel plate girders with slender cross-sections. However, there is a lack of guidance for the fire design of steel plate girders subjected to shear buckling. After the evaluation of the contribution from the flanges to shear buckling resistance in previous works, an extended numerical analysis has been carried out, dealing with the evaluation of the shear buckling resistance of steel plate girders at both normal and elevated temperatures. The numerical results have been compared with those obtained from the application of the Eurocode 3 (EC3) design expressions. A methodology for analysis of the results, which considers three failure zones based on shear-bending interaction diagram, has been used in order to compare the numerical results with the analytical expressions. Moreover, maintaining the EC3 principles, a new expression for the contribution from the web to shear buckling resistance is presented for both normal and elevated temperatures. Finally, a study on the influence of the girders geometrical relations on the increase of strength provided by the rigid end post has been performed.

ABSTRACT: Recent measurements made by our research group of a super-large cooling tower indicate that its fluctuations in wind-induced responses exhibit a degree of nonstationarity, echoing similar observations.
reported for other structures. This might cause errors in estimates of extreme responses and misunderstanding of wind-induced effects if nonstationarity is neglected. In this study, the wind-induced response signals of a super-large cooling tower (height 190 m) in a coastal region were measured for the first time under real Reynolds number and turbulent flow conditions. After noise reduction had been performed, nonstationarity of the signals was identified within various time intervals. The mean wind effect, pulsating wind effect, probability density distribution, dynamic amplification factor, and extreme responses of the super-large cooling tower were studied based on stationary and non-stationary models. Finally, the power spectral density (PSD) and evolutionary power spectral density (EPSD) of the wind-induced response signal were analyzed. The resonance spectral expression of wind-induced responses at resonance excitation points, which is applicable to super-large cooling towers, is summarized. The wind-induced responses presented strong nonstationarity. Non-stationary models that consider response nonstationarity are important in the authentic assessment of the extreme responses of super-large cooling towers. The extreme constant calculated by the stationary model cannot provide an adequate assurance rate and reduces the economic efficiency of extreme response estimates. The vibration energy distributions of resonance excitation points in different regions of the cooling tower were similar, but the PSD functions at quasi-static points were dramatically different from each other. The energy distribution of the resonant excitation points showed a phased trend, and the proposed resonance spectral expression considers three stages of variation in the PSD function of the responses to achieve high predictive accuracy.

ABSTRACT: Traditional buckling experiments of imperfection-sensitive structures like cylindrical shells can cause the permanent failure of the specimen. Nevertheless, an experimental campaign is crucial for validation of the design and numerical models. There is, therefore, interest in nondestructive methods to estimate the buckling load of such structures from the prebuckling stage. The vibration correlation technique allows determining the buckling load without reaching the instability point. Recently, a novel empirical vibration correlation technique based on the effects of initial imperfections on the first vibration mode demonstrated interesting results when applied to composite and metallic unstiffened cylindrical shells. In this context, this paper explores this novel approach for determining the axial buckling load of a metallic orthotropic skin-dominated cylindrical shell under internal pressure, which represents a simplified downscaled model of a launcher propellant tank. An experimental campaign consisting of buckling tests and noncontact vibration measurements for different axial load levels is conducted considering the specimen without and with three different internal pressure levels. The experimental results validate the above-mentioned vibration correlation technique for determining the axial buckling load of pressurized cylindrical shells. Moreover, finite element models are calibrated in order to evaluate the frequency variation within a broader and dense range of the axial loading leading to an assessment of the considered maximum load level and number of load steps as related to the deviation of the estimation. The results corroborate the applicability of the vibration correlation technique as a nondestructive experimental procedure to assess the axial buckling load of imperfection-sensitive orthotropic skin-dominated cylindrical shells under internal pressure.

Junyan Zhang, Bingquan Lu, Danfeng Zheng and Zhongyu Li (State Key Laboratory of Automobile Simulation and Control, Jilin University, Changchun 130000, China), “Axial crushing theory of metal-FRP hybrid square tubes wrapped with antisymmetric angle-ply”, Thin-Walled Structures, Vol. 137, pp 367-376, April 2019, https://doi.org/10.1016/j.tws.2019.01.005

ABSTRACT: Hybrid square tubes wrapping fiber reinforced polymer (FRP) around metallic tubes are excellent structures for both collision energy absorption and lightweight. This paper deals with axial crushing theory of hybrid square tubes wrapped with antisymmetric angle-ply. The energy dissipation mechanism of hybrid square tubes is analyzed based on deformation of metallic square tubes. Considering the effects of stacking sequences of FRP on the crashworthiness and energy absorption, theoretical expressions of the membrane force and fully plastic bending moments per unit length of hybrid squares tube are derived. Then, the expression of mean crushing force of hybrid square tubes wrapped with antisymmetric angle-ply is established. Theoretical
predictions compare well with the results of three groups of experiments and forty simulation models. The theoretical calculation presented in this paper can predict the behavior of hybrid square tubes during the conceptual design.

ABSTRACT: This paper systematically investigates the low-velocity impact response and resulting damage behavior of aluminum honeycomb sandwich structures with carbon fiber reinforced plastic (CFRP) face sheets by combining the experimental and numerical methods. Low-velocity impact tests are conducted to determine and quantify the effects of structural parameters, such as face sheet thickness, cell wall thickness, honeycomb core height and hexagon side length, on the impact load, energy absorption, and failure mode. To further elucidate the impact behavior, a user VUMAT subroutine is developed to predict the progressive failure behavior of composite face sheets. Numerical simulation is performed to characterize the impact response and explore the deformation/failure mechanisms. The predicted impact load, energy absorption, contact time and failure mode agree well with measured counterparts. These studies reveal the face sheet thickness has particularly significant influence on the impact resistance performance of honeycomb structures. Cell wall thickness and side length of honeycomb core have notable effect on the impact load and structural stiffness of such structures, while which do not play a great role in energy absorption. Increase in core height has comparatively little effect on initial stiffness and energy absorption but makes the second peak loads decreasing for the perforation cases.

Vuon Nguyen Van Do, Thanh Hi Ong and Chin-Hyung Lee (First author is from: Applied Computational Civil and Structural Engineering Research Group, Faculty of Civil Engineering, Ton Duc Thang University, Ho Chi Minh City, Vietnam), “Isogeometric analysis for nonlinear buckling of FGM plates under various types of thermal gradients”, Thin-Walled Structures, Vol. 137, pp 448-462, April 2019, https://doi.org/10.1016/j.tws.2019.01.024

ABSTRACT: This study attempts at analyzing buckling responses of functionally graded material (FGM) plates under diverse types of thermal loadings. An accurate and effective numerical approach based on isogeometric analysis (IGA) to predict the nonlinear thermal buckling behavior is developed. A refined higher-order shear deformation theory (HSDT) which accounts for the geometric nonlinearity in the von Kármán sense is presented and used to derive the equilibrium and governing equations for FGM plate in thermal environments. Two different types of transverse shear functions are considered in the refined HSDT. IGA uses non-uniform rational B-spline (NURBS) basis functions which enable to accomplish easily the smoothness of arbitrary continuity order. Thus, the present method satisfies the C-continuity of the displacement field required by the proposed HSDT. Several numerical examples involving buckling behavior of various kinds of FGM plates subjected to uniform, linear and nonlinear temperature distributions across the thickness are simulated, and the results are compared to the analytical solutions for the verification purpose. Parametric studies are also carried out on FGM plates under the different through-thickness temperature variations to scrutinize the thermal buckling features. Temperature gradient through the thickness by the one-dimensional (1-D) heat conduction and thermal profile developed by the three-dimensional (3-D) heat conduction are also taken into account. Results demonstrate that the proposed IGA method can be used as an accurate and effective numerical tool for analyzing the thermal buckling responses of FGM plates, and the 3-D heat conduction needs to be considered in the buckling analysis of FGM plates subjected to thermal conduction.

ABSTRACT: It is necessary to master the propagation and distribution of the overpressure on a building under an explosive load before an anti-explosion design is achieved. However, there is very less available test data which can be applicable to multi-curved large-span space structure under a surface burst. In this work, a series of tests were performed to study the wave diffraction behaviour of a hemispherical structure by changing the
nearest distance between the charge and structure and TNT equivalent. The purpose of the experiment was to develop an experimental dataset which could evaluate the accuracy and efficiency of the numerical model. A simplified method to study the blast load distribution on the hemispherical structure was proposed by numerical and geometric analysis. The numerical results showed that the peak overpressure, impulse, blast wave front arrival time, and positive phase duration were highly dependent on the span–distance ratio and span–charge ratio, which affect the significance of the reflecting and shielding effects. For a convenient engineering application, a series of pseudo-analytical formulas were suggested to estimate the pressure–time histories for an ideal hemisphere structure.

ABSTRACT: This paper focuses on the buckling of thin-walled confined liner with grouting voids, subjected to uniform external pressure. Based on the analytical and numerical results for three different void lengths, the single lobe deformation of the liner is observed for small void length; the double lobes deformation occurs for the medium void length, and single lobe deformation is found for large void length. Small grouting voids show negligible effects on the confined liner, and the critical buckling pressure can be predicted analytically by Glock's model. The analytical expressions of buckling pressure for medium and large voids are developed analytically and numerically in the present work. Analytical solutions are based on the principle of minimum potential energy and admissible displacement functions. In the numerical analysis, a two-dimensional (2D) finite element model (FEM) is developed by tracing the pressure-displacement equilibrium paths to obtain the critical buckling pressure. Both the analytical and numerical results show the medium and large grouting voids significantly reduce the buckling pressure. The numerical equilibrium paths and critical buckling pressures excellently agree with their corresponding analytical solutions.

ABSTRACT: Experimental study is carried out to investigate the behavior and strength of square hollow structural section (SHS) columns, strengthened with an innovative polymer-mortar system. Thirteen specimens of cold-formed SHS columns with different variables are chosen. Three short-column and ten long-column SHS specimens were experimentally tested. The local and overall buckling of specimens are measured in the laboratory. The tested specimens are subjected to an axial compressive load. The effect of the thickness of polymer-mortar applied directly to the well-prepared steel surface was studied. The effect of slenderness ratio \((kL/r)\) and width-to-thickness ratio \((b/t)\) on the effectiveness of mortar strengthening was also discussed. Different failure modes are discussed as well as complete axial strength curves are drawn for different cross-sections and member lengths. A maximum axial strength gain of 31.6% was achieved for SHS short columns strengthened with 6 mm thickness polymer-mortar layer. For long columns, a maximum strength gain of 76.7% was achieved with 6 mm thickness polymer-mortar layer applied on four sides. In all mortar-strengthened SHS short and long columns, the axial and lateral deflection, and the axial strain were reduced. The axial strength of SHS long slender columns increased greatly as the overall slenderness ratio increases.

ABSTRACT: Both symmetric and anti-symmetric post-buckling of the notched tension sheets are modelled using the spline finite strip method to study the nonlinear effects of the post-buckling state on stress and displacement fields. Nonlinear elastic fracture mechanics is introduced to consider the effect of post-buckling state on the fracture behaviour and new stress intensity correction factors are defined for the buckled notched sheets. Finally, analytical approaches were provided to evaluate the fracture capacity and the fatigue life of the
notched sheets in the presence of buckling. The remarked outcomes were verified by the existing analytical, numerical and experimental results.

ABSTRACT: A novel and effective computational approach within the context of isogeometric analysis (IGA) is developed for analyzing size-dependent mechanical behaviors of functionally graded (FG) microbeams. To capture the size effects, an extension of quasi-3D theory is established to integrate with the modified couple stress theory. The nonuniform rational B-spline (NURBS) basis functions are employed and can directly meet the first-order derivative demand of the quasi-3D theory, where four variables are involved at each node. In this new setting, both normal and shear deformations are considered, while the shear correction factor is avoided. Numerical examples are studied, in which the effects of several factors, including material gradient factor, boundary conditions, parameter of material length scale, and aspect ratio, on deflections, stresses, and fundamental frequencies of FG microbeams are explored.

ABSTRACT: This paper reports a series of experimental and analytical assessments on the flexural behaviour of cold-formed thin-walled lipped-channel section truss (CTLST) beams with profiled steel sheeting-concrete (PSSC) slabs or autoclaved lightweight concrete (ALC) slabs. Three test parameters were studied, including the floor type, the U-shaped shear connector, and the connection type among CTLST members. Besides, testing phenomena, failure modes, load versus deflection curves, and strain response for these CTLST composite beams were also analyzed. The experimental data showed that flexural strength of CTLST composite beam was significantly increased by adopting reliable connection type; bond performance of the interface between the profiled steel sheeting (PSS) and concrete slab was improved by erecting U-shaped shear connectors. These CTLST composite beams were in accordance with specification recommendations of deflection limits. In addition, three-dimensional finite element (FE) modelling of CTLST composite beams were developed and verified by test data. Effect of material and geometrical parameters on the flexural feature of the CTLST beams with PSSC slabs was explored. Finally, a simplified method, which was verified by the tested and simulated results, was proposed to predict the mid-span deflection of the CTLST composite beam using reliable connection type under serviceability loads.

ABSTRACT: Thin-walled cylindrical tubes have been renowned as an ideal energy absorber in aerospace and automotive industries for their lightweight potential and extraordinary energy absorbing capability. In this research article, systematic investigations on the specific energy absorption characteristics and lateral crushing behaviour of deep drawn non-capped and plain end-capped cylindrical tubular structures were performed. Initially, finite element models were developed with ABAQUS/CAE® code to predict the deformation characteristics of the proposed tubes under quasi-static lateral compression. Subsequently, detailed experimental studies on the aluminium cylindrical tubes of various thickness (1.63 mm, 2.04 mm and 3.25 mm) under lateral quasi-static loading have been performed and the lateral crushing force-deformation histories obtained were analyzed. The lateral deformation response of the proposed tubes under impact lateral loading has been studied further and analyzed with the validated finite element model. Also, the impact crushing performance of the plain end-capped cylindrical tubes was related to the non-capped cylindrical tubes and within tested samples, the plain end-capped tubes absorbed 0.8–1.6 times more specific energy than the conventional non-capped cylindrical tubes. Finally, it was found that the plain end-capped tubular structures exhibit desirable force–
deformation characteristics such as uniform crushing force with a long crush stroke and maximum energy which is very important in the design of energy absorbers for transverse direction.

ABSTRACT: This paper presents and discusses numerical results concerning the (i) elastic local and distortional post-buckling behaviours and (ii) imperfection sensitivity of regular convex polygonal cross-section (RCPS) simply supported tubes under uniform compression (columns). Although it was shown recently that the local and distortional buckling behaviours may be often characterised by duplicate bifurcation modes, knowledge concerning the corresponding post-buckling behaviour is still lacking. The results presented are obtained through a geometrically non-linear Generalised Beam Theory (GBT) formulation previously reported by the authors. This GBT formulation is first employed to characterise the column bifurcation behaviour, namely by helping to pinpoint the occurrence of the above two distinct buckling behaviours. Then, post-buckling results are presented and discussed for (i) different combinations of the local-to-distortional buckling load ratio and the (ii) amplitude of the critical-mode initial geometrical imperfections, in order to characterise the RCPS column imperfection sensitivity. Such results provide the evolution, along given equilibrium paths, of the column deformed configurations (expressed in GBT modal form), relevant displacement profiles and participation diagrams based on either stress resultant strain energies or amplitude functions. For comparison and validation purposes, ABAQUS shell finite element values are reported.

ABSTRACT: This paper intends at numerically analyzing the simultaneous influences of base-isolator system and vertical baffle on the seismic performance of a three-dimensional (3D) rectangular liquid storage container, presuming irrotational, inviscid, and incompressible flows. A boundary element technique with meaningful computational efficiency is primarily formulated to treat the spectral problem of liquid motion using the zoning method including the velocity potentials alone of the half free-surface length, which is coupled with Finite elements for tank wall using equilibrium and compatibility conditions. In the soil/foundation component, the foundation is modeled by shell finite elements and the half-space soil medium is modeled employing the external boundary elements, which fulfill the radiation condition of homogeneous media. Eventually, above two parts are attached to equation for isolator motion in the time domain, to attain the total system’s nonlinear seismic response. The validity and efficiency of the present coupled numerical method is confirmed against available theoretical solutions and numerical predictions, revealing a good agreement with benchmark results. The sensitivity of base forces, the maximum hydrodynamic pressure and liquid oscillation in relation to some system parameters involving the baffle height, the base-isolator stiffness and the soil properties have been highlighted.

ABSTRACT: Cold-drawing is one of the typical cold-forming techniques in producing stainless steel circular hollow sections (CHS). Compared with cold-rolling, cold-drawing can produce large scale stainless steel tubes which have wide applications in highly corrosive environment. Nevertheless, few researches have been carried out on the duplex stainless steel CHS columns. In this paper, cold-drawn duplex S22053 stainless steel CHS of three types of cross-sections were tested, including 8 material tensile coupon tests, 6 axially compressed stub column tests and 7 axially compressed long column tests. The material stress-strain curves of the cold-drawn CHS tubes, ultimate loads and failure modes of the stub and long columns were obtained. It has been revealed that material properties of cold-drawn stainless steel CHS tubes are close to those of the virgin plate in the
annealed state. Moreover, all the stub columns show local buckling in “elephant foot” mode, while all the long columns undergo overall flexural buckling, among which a long column specimen with the nominal length of 700 mm (CHS-700) shows local buckling after the peak load due to the interaction of axial compression and second-order bending moment. Furthermore, comparing the test values with the predicted values based on the European, American, Australian/New Zealand and Chinese design codes, and the calculation methods available in literatures, it is concluded that the predicted values of the stub columns and the long columns with relatively large member slenderness are all lower than the test values, while the predicted values using the design methods except that in the Chinese design code are higher than the test values for the long columns with relatively small member slenderness. Chinese design code could provide safety predictions for cold-drawn duplex stainless steel CHS columns.

Mizan Ahmed, Qing Quan Liang, Vipulkumar Ishvarbhai Patel and Mohammad N.S. Hadi (First and Second authors are from: College of Engineering and Science, Victoria University, PO Box 14428, Melbourne, VIC 8001, Australia), “Numerical analysis of axially loaded circular high strength concrete-filled double steel tubular short columns”, Thin-Walled Structures, Vol. 138, pp 105-116, May 2019, https://doi.org/10.1016/j.tws.2019.02.001

ABSTRACT: Circular high-strength concrete-filled double steel tubular (CFDST) columns are high performance members where the internal and external steel tubes offer significant confinement to the concrete infill. The confinement remarkably improves the concrete compressive strength and ductility. However, no fiber element models have been formulated for computing the responses of CFDST columns with circular steel tubes filled with high-strength concrete incorporating accurate confinement to the core and sandwiched concrete. In this paper, a new fiber-based numerical model is developed that computes the axial load-strain responses of circular high-strength CFDST short columns under axial loading. Based on existing experimental results, a new confining pressure model is developed for the determination of the confining pressures on the core-concrete in CFDST columns with circular sections. A new strength degradation parameter is also proposed that allows the concrete post-peak characteristics to be quantified. The fiber-based numerical model validated by experimental data is used to assess the responses of high-strength CFDST columns considering important parameters, which include the inner steel tube, external tube diameter-to-thickness ratio and concrete and steel strengths. A simple expression is derived for the estimation of the axial load-carrying capacities of circular short CFDST columns and comparisons with several design codes are made. The proposed fiber-based analysis technique and design equation can accurately determine the responses of short circular high-strength CFDST columns.

ABSTRACT: The impact performance of lightweight structures represents an important design criterion in modern applications. Within this framework, the self-reinforced PET (poly-ethylene terephthalate) materials prove to exhibit large deformations till failure, which enables them to be proper candidates for impact energy absorption. Apart from the advantages offered by the lightweight characteristics, they are made of recyclable materials, an additional reason for their consideration in engineering applications. In this paper, the behavior of a hierarchical sandwich structure made out of self-reinforced PET (matrix & fibre) combined with PET foam is numerically investigated with respect to the specific energy absorption (SEA) capacity in out-of-plane quasi-static loading conditions. The numerical model of the structure is developed and its behavior is firstly validated through experimental tests. The specific energy absorption is further on determined for several geometric configurations of the hierarchical sandwich structure and compared with the behavior of other cellular structures found in the technical literature. A competitive behavior is observed with respect to impact energy absorption.

ABSTRACT: The paper presents the findings of a pioneering study investigating the newly developed polymer-aluminium alloy hybrid foam as fillers of thin-walled square tubes made of aluminium alloy, as an alternative to the conventional closed-cell aluminium foams. The hybrid foam filled structures were prepared by infiltrating an aluminium alloy open-cell foam with silicone or epoxy inside the thin-walled tubes. Quasi-static and dynamic crush compressive response, deformation and failure modes and energy absorption characteristics of the hybrid foam filled structures were evaluated and compared to the empty tubes and tubes filled with conventional aluminium alloy open-cell foam (with voids). Results show that the deformation of the square thin-walled is improved due to the open-cell foam filler. It stabilises the tube and prevents the unstable global bending mode or a mixed buckling mode that is considered as an inefficient mode from the crashworthiness point of view. The deformation of the hybrid foam filled tubes was accompanied with a progressive folding mode. It was also observed that the polymer fillers caused the rupture of the outer tube at the corners, which results in higher energy apportion but might limit their application. However, it was found that the most efficient hybrid foam filled structures studied, in terms of crashworthiness, were the tubes filled with the epoxy-aluminium alloy hybrid foam. An increase of 610% and 300% in energy absorption and 78% and 51% in specific energy absorption of hybrid foam filled structures with length of 25 mm and 50 mm in comparison to the empty tubes (at strain of 0.7) was noted, respectively.

ABSTRACT: Steel sections in steel-concrete composite columns have been proofed to be less susceptible to local buckling and have higher capacity than bare steel columns, attributed to the internal restraints provided by the infilled concrete. This article presents a theoretical study concerning the local and post-local buckling of fabricated normal and high strength steel sections filled with concrete, including concrete filled steel tubular (CFST) sections and partially encased composite (PEC) sections. A nonlinear finite element (FE) model was established and validated to simulate the behavior of steel plates in contact with concrete, with both geometric imperfections and residual stresses explicitly incorporated. This model was subsequently applied in a parametric study to investigate the effects of several critical factors on the local buckling behavior of box and I steel sections. Based on the available test and FE results, new design formulas were proposed to predict the local buckling and post-buckling ultimate strengths of concrete-restrained steel box and I sections, taking into consideration high material strengths, residual stresses and geometric imperfections. The enhancement of strength due to the presence of concrete infill was confirmed through a comparison with the post-buckling strength of bare steel sections. Recommendations were also made for design purpose based on the formulas proposed.

ABSTRACT: Stress analysis of thin-walled composite laminated box beams having variable stiffness is realized in this study based on an analytical model accounting for flexural-torsional coupling and warping effects. The variable stiffness of the beam is acquired by constructing laminates with curvilinear fibers having certain specific paths. The fiber paths of variable stiffness layers are classified in three groups as antisymmetric, symmetric and asymmetric. A displacement based finite element method is used to solve the analytical model and to calculate the distributions of axial and transverse shear stresses at different locations of the cantilever composite beam subjected to the transverse and the torsional loading at its free end. Numerical results obtained are compared with available results in the literature for specific cases. A detailed investigation is performed to understand the relation between the stress distributions along the cross section of the beam and the shape of curvilinear fibers for antisymmetric and symmetric cases.

ABSTRACT: The stiffness-tailoring capability of Variable Angle Tow (VAT) laminates gives enhanced freedom to design thin-walled structures. One key advantage of tow steering is the ability to redistribute stresses improving buckling performance, leading to reduction in material weight and costs. The aim of this work is to optimise the initial postbuckling behaviour of a recently proposed VAT composite wingbox. The optimisation process is based on a fibre path parameterisation. It involves seeking the stacking sequence that minimises the displacements occurring in the postbuckling regime. This problem is solved by coupling the multi-modal Koiter asymptotic approach implemented with a solid-shell Finite Element environment through stochastic optimisation strategies. Results obtained regarding different optimisation scenarios show a much improved performance for the buckling and postbuckling response of the wingbox with respect to the initial VAT design. Additionally, manufacturing constraints are readily included in the optimisation program. The possibility of performing an efficient and robust optimisation process of a complex structure with a multi-modal Koiter asymptotic approach is demonstrated, showing its viability as a design tool for buckling dominated structures. A parametric study regarding the influence of steering radii shows that overcoming the current manufacturing constraint on minimum radius is worthy of investigation.

ABSTRACT: A number of classic problems in the stability of thin walled structures in the elastic-plastic range which have been examined to some extent by the present author over the years are collected and discussed in order to highlight the advantages and drawbacks of analytical and numerical approaches. Issues related to the modes interaction, to the material modelling and to the imperfection sensitivity are examined with respect to well-known conundrums in the theory of stability and it is shown that the combination of all these aspects is such that any numerical analysis, despite the availability of modern very powerful nonlinear FE packages, must be preceded by a careful examination of the particularities of the problem at hand. In fact, a capable insight into the mechanics of the problem is shown to remain paramount in order to attain a good agreement with experimental results and provide reliable predictions for a large number of engineering tasks.

ABSTRACT: This paper presents an experimental investigation of the mechanical behaviour of the concrete-filled double-skin tube (CFDST) with stiffeners. A total of 40 CFDST columns were prepared and subjected to axial and eccentric loading. The failure modes and ultimate load-bearing capacities, together with the deformation and strain responses of the specimens, were analysed. The effects of the stiffener type, slenderness ratio, and eccentricity ratio were researched in this study. The test results indicated that the ductility of the CFDST specimens was improved greatly by the presence of stiffeners, which gave a lower load-bearing capacity owing to the reduction in the effective area of the inner concrete. Moreover, an analytical-numerical model was developed to analyse the mechanical behaviour of the CFDST specimen, and an improving mechanism was considered. In addition, theoretical estimations to predict the ultimate load-bearing capacities of CFDST specimens subjected to axial and eccentric loading were established. These estimations showed good agreement with the theoretical results and the test results.

ABSTRACT: This study examines the previous experimental results of ratcheting behavior of elbow pipe made of Z2CN18.10 austenitic stainless steel subjected to constant internal pressure and reversed in-plane bending by Chen-Jiao-Kim (CJK) kinematic hardening model as a user subroutine of ANSYS. A set of more precise CJK
model parameters were determined. Based on the new model parameters, the evolutions of ratcheting behavior of pressurized elbow pipe were made under two sets of different loading paths. The paths consist of the alternation of internal pressure and bending moment, and bending-torsion combination under constant internal pressure. The preliminary results claim that different loading paths have a significant effect on ratcheting behavior of pressurized elbow pipe.

ABSTRACT: Variable angle tow (VAT) composites have demonstrated better performance in buckling and post-buckling over straight fiber composites based on the mechanics of load redistribution from critical regions to supported edges. In this work, the dynamic instability behavior of a curved VAT composite panel subjected to periodic axial compression load is investigated. The governing energy functional of a curved symmetric VAT panel under external loading is derived using Donnell's shallow shell theory. Later, the discretized equations of motion are derived using the Rayleigh–Ritz method combined with the generalized differential integral quadrature method (GDIQM). Initially, the pre-buckling problem is solved by applying a uniform compression load to compute the stress resultant distribution which is used to evaluate the buckling load of the curved VAT panel. Subsequently, the dynamic/parametric instability region of a curved VAT panel subjected to periodic axial compression load is determined using Bolotin's first-order approximation. Then, the dynamic instability performance is evaluated for a curved VAT panel with linear fiber angle distribution and compared with straight fiber laminates. Finally, the influence of fiber angle orientation, the radius of curvature, aspect ratio and plate boundary conditions on the dynamic instability of VAT panel is presented.

ABSTRACT: In this paper, comprehensive studies on the size-dependent thermal post-buckling and coupled bi-directional transverse-longitudinal free vibration behavior of post-buckled rotating pre-twisted functionally graded (FG) microbeams in thermal environment are presented. The material properties are assumed to be temperature-dependent and graded in the thickness direction with mid-plane symmetric distribution, i.e., symmetric functionally graded (S-FG). At first, the discretized nonlinear post-buckling governing equations are derived based on the modified strain gradient theory (MSGT) in conjunction with the first-order shear deformation theory (FSDT) of beams under the von Kárman geometric nonlinearity assumptions using Hamilton's principle and Chebyshev-Ritz method. The resulting nonlinear equations under different boundary conditions are solved iteratively by employing Newton-Raphson's method. Then, using the same theories and solution procedure, the free vibration equations around the post-buckled configuration are derived and solved. After validating the approach, the effects of angular velocity, twist angle, length scale parameters, thickness-to-length ratio, hub radius, material gradient index and boundary conditions on the post-buckling equilibrium path and linear free vibration behavior of rotating pre-twisted S-FG microbeams are investigated. The results are prepared for both linear and nonlinear variations of the twist angle along the microbeam axis.

ABSTRACT: This article presents some observations related to the phenomenon that occurs when transversally and longitudinally stiffened steel plate girders are subjected to patch loading. The failure mechanism differs considerably for the particular structural case of girders with largely spaced transverse stiffeners, which have been studied thoroughly in last decades. Steel plate girders with closely spaced stiffeners are occasionally found in bridge design and for such cases, the current EN1993-1-5 rules underestimate the strength of the webs to transverse forces. Research work on girders with closely spaced transverse stiffeners is available but for such cases, the web plates are longitudinally unstiffened. Some comparisons between the results obtained and those
provided by EN1993-1-5 are discussed. Preliminary results suggest that the resistance of densely stiffened steel girders (both transversally and longitudinally) must be studied and subsequently revised accordingly. In addition, it is pointed out that a certain degree of imperfection sensitivity is inferred from the results. Further studies on this topic are necessary.

ABSTRACT: This work presents and discusses numerical results of an ongoing investigation concerning the elastic post-buckling behaviour and imperfection sensitivity of regular convex polygonal cross-section (RCPS) tubular columns affected by local-distortional (L-D) interaction. This investigation is conducted by means of geometrically non-linear Generalized Beam Theory (GBT) analyses, extending the knowledge on the “pure” local and distortional post-buckling behaviours of RCPS tubes recently reported by Martins et al. [1]. Due to their inherent modal nature, the GBT analyses make it possible to acquire in-depth knowledge on the structural behaviour of RCPS tubes and also to include, in a straightforward fashion, arbitrary member initial geometrical imperfections. Columns with distortional-to-local critical buckling load ratios (i) close to 1 (“true L-D interaction” – the most trivial L-D interaction type) and (ii) significantly above 1 (“secondary-distortional bifurcation L-D interaction” – the most relevant L-D interaction type) are investigated. Local/distortional critical-mode initial geometrical imperfections and (linear) combinations of both are considered in the former columns, while only local initial imperfections are dealt with in the latter ones – several amplitudes are dealt with to assess the imperfection sensitivity. For comparison and validation purposes, ABAQUS shell finite element analysis results are also reported.

ABSTRACT: The influence of flexural anisotropy or bend-twist coupling on the buckling performance of CFRP composite plates in compression and shear and thin-walled CFRP composite tubes in torsion is examined in this paper using the finite strip method of analysis. The finite strip formulation employed in the analysis procedure is readily able to deal with the many complexities associated with typical laminated composite construction. Lay-up configurations resulting in membrane anisotropy, flexural anisotropy and membrane-flexural coupling are all easily dealt with. The strip perturbation or buckling displacement fields are postulated to vary sinusoidally along the strip length and algebraically across the strip width and any combination of linearly varying bi-axial tension or compression coupled with in-plane shear loading on the strip can be accommodated. The paper gives an in-depth understanding of the complex buckling mechanics associated with flexural anisotropy in polymer composite construction and highlights the importance of realising the significance of the applied in-plane shear or torque direction on buckling performance. Markedly different stability levels are shown to be in existence for the load cases of positive and negative shear in composite plates and for the clockwise and anticlockwise torsional loading of thin-walled composite tubes. This situation is, of course, not realised in isotropic metal construction or in orthotropic composite construction since such material systems are devoid of the effects of bend-twist coupling.

ABSTRACT: In this study, additively manufactured aluminum thin-walled tubes with different slit dimensions are proposed to improve energy absorption efficiency. A total of 18 samples, which varied in the number of slits, slit length, slit width, and slit ends, were tested under quasi-static axial compression at a rate of
20 mm/min. The deformation and failure modes, load-displacement curves, and a number of crashworthiness factors were investigated. The factors considered included, but were not limited to, the specific energy absorption, crushing force efficiency, and energy absorbed per stroke. The results indicated that all the considered physical parameters, except for the slit ends, had an influence on the crashworthiness of the structures. The initial peak load decreases significantly as the number, width, and length of the slits increase. The bulk of the tested tubes exhibited a crushing force efficiency greater than 0.8. Overall, the presence of slits with length 15 mm and width 5 mm resulted in lower and smoother crushing forces than the straight tubes and, therefore, greater crushing force efficiency, validating them as crashworthy structures.

ABSTRACT: The existing studies on thin-walled structures have focused on structural optimization mainly for enhancing crashworthiness and lightweighting, whilst relatively little attention has been paid to analysis of cost efficiency of an optimized structure. How to develop cost-effective products has always been a primary goal pursued by enterprises in different ways. To address this issue, this study aims to elucidate a systematic approach for exploring the effects of various material grades and structural dimension (e.g. wall thickness) on cost efficiency relative to the crashworthiness performance by taking the double-hat (DH) thin-walled structure as an example. First, a series of drop-weight tests for the DH structure are carried out under axial and lateral impacts. The experimental results show that different material grades and dimensions have different effects on the crashworthiness under different impact velocities. Second, the finite element (FE) models are established and validated with the experiments to analyze the effects of the three factors (wall thickness, material grade, and impact velocity) on the crashworthiness criteria. Third, the surrogate models for each crashworthiness performance indicator and cost efficiency (namely, specific energy absorption – SEA, bending moment – Mb, SEA/cost and Mb/cost) are constructed by using the regression technique. Finally, the combined effects of material grade and structural dimension on cost and performance are analyzed and compared respectively; and the results show that there is room to significantly reduce production cost without sacrificing the crashworthiness performance. For mass production implemented in modern automotive industry, the proposed design methodology allows to better balance performance and cost.

ABSTRACT: The existing studies on thin-walled structures have focused on structural optimization mainly for enhancing crashworthiness and lightweighting, whilst relatively little attention has been paid to analysis of cost efficiency of an optimized structure. How to develop cost-effective products has always been a primary goal pursued by enterprises in different ways. To address this issue, this study aims to elucidate a systematic approach for exploring the effects of various material grades and structural dimension (e.g. wall thickness) on cost efficiency relative to the crashworthiness performance by taking the double-hat (DH) thin-walled structure as an example. First, a series of drop-weight tests for the DH structure are carried out under axial and lateral impacts. The experimental results show that different material grades and dimensions have different effects on the crashworthiness under different impact velocities. Second, the finite element (FE) models are established and validated with the experiments to analyze the effects of the three factors (wall thickness, material grade, and impact velocity) on the crashworthiness criteria. Third, the surrogate models for each crashworthiness performance indicator and cost efficiency (namely, specific energy absorption – SEA, bending moment – Mb, SEA/cost and Mb/cost) are constructed by using the regression technique. Finally, the combined effects of material grade and structural dimension on cost and performance are analyzed and compared respectively; and the results show that there is room to significantly reduce production cost without sacrificing the crashworthiness performance. For mass production implemented in modern automotive industry, the proposed design methodology allows to better balance performance and cost.

ABSTRACT: This paper is mainly focused on the longitudinal residual stress of cold-formed thick-walled square hollow section (SHS) and rectangular hollow section (RHS) annealed and non-annealed steel tubes. The sectioning method was used to study the longitudinal residual stress. It was found that the longitudinal residual
stress consisted of bending and membrane components and the magnitude of residual stress was mainly influenced by factors such as thickness \((t)\), depth to thickness ratio \((D/t)\), depth to outer radius ratio \((D/R)\), yield strength of flat plate \((f_y)\) and tensile strength to yield strength ratio of flat plate \((f/f_y)\). On this basis, the distribution models were proposed separately for annealed and non-annealed specimens and it was proved to have a high accuracy. Finally, a comparison was made between the annealed and non-annealed specimens and it was found that the bending and membrane residual stress of annealed specimens could be reduced by about 80% and 50% respectively which means that the annealing process could significantly reduce the longitudinal residual stress.

ABSTRACT: This paper presents the generalisation of an energy-based method for the modal decomposition of buckled shapes of thin-walled members. This comprehensive method is derived and validated for fully decomposing the elastic buckling solution of a thin-walled member into the pure buckling mode classes of global, distortional, local, shear and transverse extension. The first three modes are de-facto prerequisites for buckling capacity predictions found in current design standards for thin-walled structures. In the literature, two main methods, namely the generalised beam theory (GBT) and the constrained finite strip method (cFSM), are widely employed for modal decomposition. Recently, an alternative energy-based approach has been presented for the decomposition of buckling modes into the classical local, distortional and global modes. This method is generalised in the present study to achieve a complete decomposition that also accounts for shear and transverse extensional modes in addition to global, distortional and local modes. In this method, each of the buckling classes is separated by imposing constraints that are defined by enforcing specific criteria on the total strain energy of the member. The adopted criteria are based on the fundamental mechanical assumptions of the GBT which were also implemented in the conventional cFSM and later were further detailed for modal classification in the generalised cFSM. This paper is accompanied by a paper in which derivation of a modified global torsion mode for sections with closed loops is presented and the applicability of the proposed method is demonstrated using a series of numerical examples.

ABSTRACT: This paper is a companion to (Khezri and Rasmussen, 2019) [1], where the generalised strain energy-based method for the modal decomposition of buckled shapes of thin-walled members is introduced. The paper presents the application of the proposed method for full modal decomposition to various thin-walled members. A series of numerical examples are presented in order to verify the robustness and capabilities of the proposed modal finite strip method (mFSM). In addition, the problem of global torsional modes in sections with closed cell(s) is revisited in this paper. In sections with closed loops, the classical global torsion modes does not exist due to presence of in-plane shear strains. In the context of the proposed energy-based method, a modified global torsion buckling mode is derived that allows for the occurrence of shear in closed cell. The pure global buckling curves obtained incorporating the modified global torsion base vectors are compared with the generalised constrained FSM (cFSM) and generalised beam theory (GBT) results. It is shown that the proposed modal decomposition method is capable to accurately capture the modal behaviour of thin-walled sections.

ABSTRACT: To obtain a strong and weight-efficient cylindrical column, we proposed a novel foam core sandwich-walled hollow column reinforced by stiffeners (FSCRS). The FSCRS was consisted of glass fibre-reinforced polymer (GFRP) faces, polyvinyl chloride (PVC) foam core, and GFRP stiffeners. Four full-diameter specimens, including two FSCRS and two traditional foam core sandwich-walled hollow columns (FSC), were

ABSTRACT: This paper presents the results of an experimental and numerical study of the behavior of circular hollow section (CHS) steel tubes strengthened by Aramid fiber-reinforced polymer (AFRP). The aramid fiber used for this experiment is available under the trade name of Kevlar 49. In this study, thin-walled circular steel tubes externally bonded with fiber in the hoop direction were tested under axial compression to examine the effects of the AFRP thickness, on their axial load carrying and shortening capacity. The three-dimensional finite element models (FEM) of AFRP strengthened circular hollow section (CHS) was developed using ANSYS Workbench Ver. 19.0 and ACP (ANSYS Composite Prep/Post) tool considering both geometric and material nonlinearities. The effects combined of AFRP damage and interlaminar failures for the bonded interface are modeled within FEM using “Hashin” failure criteria and Cohesive Zone Model (CZM), respectively, to provide an accurate simulation. The results involving the failure modes, load vs. axial shortening curve and ultimate load capacity, were obtained from the experimental and numerical simulation and compared for validation. Both the experimental and numerical results are consistent, demonstrating that AFRP external strengthening can considerably enhance the strength of steel tube columns by 96% for short tubes and 23% for long tubes using 3 mm thickness of AFRP.

Minhao Dong, Mohamed Elchalakani, Ali Karrech, Mostafa Fahmi Hassanein, Tianyu Cie and Bo Yang (First author is from: School of Civil, Environmental and Mining Engineering, The University of Western Australia, WA 6009, Australia), “Behaviour and design of rubberized concrete filled steel tubes under combined loading conditions”, Thin-Walled Structures, Vol. 139, pp 24-38, June 2019, https://doi.org/10.1016/j.tws.2019.02.031

ABSTRACT: Rubberised concrete has the benefit of utilising waste material, preventing resource extraction and improving concrete ductility, however at the cost of reduced strength and stiffness. This paper explored the option to effectively confine the rubberised concrete with steel tubes to obtain enhanced strength and ductility. The behaviour and performances of thirty rubberised concrete-filled single-skin steel tubes of various rubber content, steel section and load eccentricities was systematically investigated in this study. The results have shown that confined rubberised concrete and the restrained steel tube improved ductility of the composite section. The rubberised concrete was more effective in delaying the premature buckling failure of the steel tube compared to the more brittle normal cement concrete. The 15% rubber replacement ratio showed a good balance of strength and ductility and thus recommended for design of roadside barriers. The behaviour of the rubberised concrete filled steel tubes could be accurately predicted using existing design guidelines and safe designs can be produced. This study demonstrated the possibility of using rubberised concrete as a solution to problems that require high moment and deformation capacity, such as the roadside barriers and columns in buildings located in seismic active zones.

ABSTRACT: Taking the von Kármán geometrically nonlinearity into account, this paper presents a nonlinear finite element formulation of axially functionally graded (AFG) tapered microbeams, which is based on the modified couple stress and Euler–Bernoulli beam theory. The profiles of physical parameters such as elasticity modulus and mass density of the microbeam are assumed to be a simple power-law form along the length direction, while either width or height of the beam changes linearly in axial direction. The size-dependent
nonlinear free vibration of AFG non-uniform microbeams is analyzed by using finite element simulation. The correctness of the present analysis is validated by comparing computed results with those available for AFG tapered beams. The effects of vibration amplitude, variation of the taper ratio in cross section and gradient index of material along the length and material length scale parameter as well as boundary conditions on nonlinear fundamental frequency are discussed.

ABSTRACT: The paper investigates the stability and post-buckling states of compressed thin-walled composite struts with predamage as a result of low-velocity impact. The struts were made of a GFRP composite material with a symmetrical lay-up by the autoclave technique. The produced channel-section struts were subjected to 20J impact in different areas of the structure: on the web and on the flange. The struts with composite damage were subjected to axial compression to investigate the effect of composite material damage on the stability and operation of the structure in the post-buckling range. A numerical analysis was performed by the finite element method to compare two models of composite material damage: the proposed Simplified Damage Model (SDM) and the model developed by Fardin Esrail and Christos Kassapoglou. The limit load when the structure loses its stability was determined by the progressive failure criterion, according to which damage initiation in the composite material is based on the Hashin criterion while damage evolution is described with the energy criterion.

ABSTRACT: Stainless steel tube confined concrete (SSTCC) stub column is a new form of steel-concrete composite column in which the stainless steel tube is used to confine the core concrete without resistance to the axial load directly. It could take the advantages of both the stainless steel tube and the steel tube confined concrete columns. This paper presents the experimental investigation of circular SSTCC stub columns subjected to axial load. Meanwhile, comparative tests of the circular concrete-filled stainless steel tubes and circular hollow stainless steel tubes were also conducted. The experimental phenomena of specimens are introduced in detail and the experimental results are analyzed. Through the investigation of axial stress and hoop stress on the stainless steel tube, the interaction between stainless steel tube and core concrete is studied. The experimental results showed that the stainless steel tube provides confinement to the core concrete, increasing the compressive capacity of core concrete significantly. In addition, the confinement of stainless steel tube in SSTCC stub columns is larger than that in concrete-filled stainless steel tubes. Therefore, the load-carrying capacity of SSTCC columns is higher than that of concrete-filled stainless steel tubes. Besides, an equation was proposed to calculate the load-carrying capacities of SSTCC columns and concrete-filled stainless steel tube columns. The calculated results agree well with the experimental results.

ABSTRACT: A non-linear theory for straight thin-walled box beam (STBB) subjected to an eccentric force, considering the distortional deformation and unequal thickness of the webs, is developed to determine the buckling capacity in this paper. Due to the coupling of warping, torsion and distortion of the cross-section, the kinematic model becomes considerably complicated. The theory considers the geometric non-linear coupling caused by the non-linear terms in each deformation mode under the generalized displacement coordinate. The non-linear differential equations is discretized by Galerkin's method, which has been shown that the interaction effects can be successfully captured between the pre-buckling deflections and geometric non-linearity. The post-buckling response of the present beam model is compared with the results of the finite element simulation.
(Ansys 15.0) and F. Mohri’s method (2002), which appears to be very conservative. The formulation is solved exactly by checking the effect of the variable parameters: the width-to-height ratio of the cross-section, the load height and the thickness of the webs. The viability and effectiveness of this method has been established by comparing with other existing numerical solutions.

Haogui Fan (School of Chemical Machinery and Safety Engineering, Dalian University of Technology, No. 2 Linggong Road, Dalian, Liaoning 116023, PR China), “Critical buckling load prediction of axially compressed cylindrical shell based on non-destructive probing method”, Thin-Walled Structures, Vol. 139, pp 91-104, June 2019, https://doi.org/10.1016/j.tws.2019.02.034

ABSTRACT: Critical buckling load prediction of axially compressed cylindrical shell is investigated based on the non-destructive probing method in this paper. Finite element model of the cylindrical shell under combined axial load and radial probe is established using ABAQUS and the static modified Newton-Raphson method that uses artificial damping is chosen in the geometrically and materially nonlinear buckling analysis. By the means of repeatedly probing the shell under different prescribed axial loads, the three-dimensional representation of probe force, probe displacement and prescribed axial load is established. Based on that, the critical buckling load of the shell is predicted by the fitting curve that reflecting the relationship between the maximum probe force and the prescribed axial load. Applying this prediction method, the perfect cylindrical shell, the cylindrical shells with dimple-shape imperfections and the cylindrical shell with measured imperfections have been studied. All of the predicted results are compared with the real critical loads in buckling behavior of the shells under axial compression. Effects of poker size and probing location on the prediction results are analyzed. Results show that the critical loads for the first buckling pattern of the cylindrical shells with notable local imperfections can be predicted accurately when the shell is probed at the location with the largest imperfection amplitude. If the shell is probed away from that area, the predicted result will become much larger. Compared to the probing location, the poker size has little effect on the prediction results. For the cylindrical shell with measured imperfections, probing at the location with largest imperfection amplitude has achieved the most accurate prediction result. Besides, the predicted critical buckling loads obtained by probing at other locations are also acceptable. It is believed that for a general cylindrical shell without notable local defects, the smallest one of different predicted results obtained by probing a series of representative locations on the cylindrical shell could be regarded as the critical buckling load.

ABSTRACT: The behaviour of square steel tube confined reinforced concrete columns after fire exposure was studied experimentally and numerically in this paper. Eighteen stub columns were first heated following the ISO 834 standard fire including both heating and cooling phases, and were subsequently loaded to failure after cooling to ambient temperature. Failure modes, temperatures in specimens, axial load versus deformation curves and strains in steel tube were monitored and discussed. A finite element model was developed using the sequentially coupled thermal-stress analysis method and was validated against tests found in literatures and this study. Parametric study was performed to identify influences of key parameters, where are heating time, cross-sectional dimension, strengths of materials, steel tube to concrete area ratio and reinforcement ratio, on residual capacity and compressive stiffness. Finally, a simplified method is proposed for predicting residual cross-sectional capacity and compressive stiffness of square steel tube confined reinforced concrete columns after fire exposure.

Sadjad Pirmohammad and Sobhan Esmaeili-Marzdashti (Department of Mechanical Engineering, Faculty of Engineering, University of Mohaghegh Ardabili, Ardabil 179, Iran), “Multi-objective crashworthiness optimization of square and octagonal bitubal structures including different hole shapes”, Thin-Walled Structures, Vol. 139, pp 126-138, June 2019, https://doi.org/10.1016/j.tws.2019.03.004

ABSTRACT: This paper investigates the effects of hole shapes and dimensions on crashworthiness performance of the square and octagonal bitubal structures under impact loading. Several holes with three different shapes including rectangle, hexagon and ellipse are considered on the walls of the square and octagonal structures. For these structures, crashworthiness indicators SEA and PCF are numerically obtained.
using finite element code LS-DYNA. Based on the results, a significant improvement on the crashworthiness capacity is achieved by employing the technique of creating holes on the walls of structures; such that the hexagonal holes created on the square and octagonal bitubal structures improve the crashworthiness capacity by 60% and 42%, respectively in comparison to the corresponding conventional structures. Interestingly, all the holed structures show less PCF compared to those without hole. In the next phase, the hole dimensions are optimized using NSGA-II (non-dominated sorting genetic algorithm) and ANNs (artificial neural networks) methods to find the optimal structures. The SAW (simple additive weight) method is then implemented on the optimal structures, and the square and octagonal structures having the hexagonal holes are finally found as the best and superior energy absorbing devices. The effect of oblique loading on crushing behavior of the holed structures is also considered. According to the results, the holes created on the structure walls improve the crashworthiness capacity of structures under oblique loading, as well.

Ji-Hua Zhu, Zi-qi Li, Mei-Ni Su and Ben Young (First author is from: Department of Civil Engineering, Shenzhen University, Shenzhen, China), “Numerical study and design of aluminium alloy channel section columns with welds”, Thin-Walled Structures, Vol. 139, pp 139-150, June 2019, https://doi.org/10.1016/j.tws.2019.03.015

ABSTRACT: This paper presents a numerical investigation on aluminium alloy welded columns of channel section. Non-linear finite element models were firstly developed and validated against non-welded column test results. The materials considered in this study were aluminium alloys 6063-T5 and 6061-T6. The validated finite element models were used for parametric studies to generate numerical results for columns containing welds. In the finite element models, both ends of the columns were transversely welded to aluminium alloy end plates. Finite element models of welded columns were developed by dividing the column into two part: non-welded region and heat-affected zones. Material properties of non-welded aluminium alloys and heat-affected zone were adopted in the models. A total of 100 numerical results were newly generated from the parametric study. The numerical results were compared with design strengths predicted by the existing American, Australian/New Zealand, European and Chinese standards. The column strengths were also compared with the design strengths by the direct strength method (DSM) and the continuous strength method (CSM). Modified DSM and CSM approaches with the consideration of heat-affected zone softening effects were proposed in this study. Both modified DSM and CSM approaches were found to yield more accurate and consistent predictions for aluminium alloy welded columns. In addition, reliability analyses were performed to evaluate the reliability level of all the existing and newly proposed design rules for channel section columns containing transverse welds.

ABSTRACT: The local buckling behaviour and ultimate cross-sectional resistance of slender tubular elliptical profiles in bending are examined by means of numerical modelling. After successful validation of the numerical model against previous experimental results, a parametric study comprising 240 simulations was conducted in order to investigate the influence of cross-section aspect ratio, axis of bending, geometric imperfections and local slenderness on structural behaviour. The ultimate moments, moment–curvature relationships and failure modes obtained are discussed. It was found that, overall, postbuckling stability increases and imperfection sensitivity decreases with increasing elliptical hollow section (EHS) aspect ratio. A design method is proposed for Class 4 EHS members that reflects the reduction in resistance due to local buckling with increasing slenderness and extends the range of applicability of existing provisions. A reliability analysis was performed in accordance with EN 1990, indicating that the design methods for EHS in bending, in addition to previous design methods for EHS in compression, are suitable for use in the Eurocode framework with a recommended partial factor of unity.

ABSTRACT: In this study, three-dimensional problem of the theory of elasticity (3DPTE) for radially inhomogeneous (INH) transversally-isotropic thin hollow spheres is investigated using the asymptotic integration method. The basic relations and equilibrium equations for radially inhomogeneous transversally-isotropic thin hollow spheres are formed and inhomogeneous solutions (INHSs) and homogeneous solutions (HSs) are constructed. The built solutions completely reveal the qualitative structure of a three-dimensional stress-strain state of radially inhomogeneous transversally-isotropic spheres of small thickness and serve as an effective apparatus for solving boundary value problems, the basis for evaluating existing applied theories and for creating new, more refined applied theories. Asymptotic formulas are obtained that allow the calculation of the three-dimensional stress-strain state of spheres. New solution groups (boundary layer solutions) have been found that are absent in applied theories. The behavior of homogeneous solutions in the inner parts of the sphere and in the vicinity of conical sections has been studied, when the thin-walled parameter of the sphere tends to zero. The nature of the constructed homogeneous solutions is clarified. On the basis of the theoretical analysis, three types of the stress-strain state (SSS) in the radially inhomogeneous transversally-isotropic hollow spheres (RINHTIHSs) are considered: a penetrating stress state, a simple edge effect, and a boundary layer. Finally, numerical calculations are made and the influences of inhomogeneity on the stress distributions are investigated.

ABSTRACT: This paper reports an in-depth and extensive numerical investigation aimed at assessing the accuracy of the current Direct Strength Method (DSM) design curve in predicting the failure load of cold-formed steel columns collapsing in global modes, namely flexural or flexural-torsional modes. This study concerns fixed-ended columns with a wide variety of cross-section shapes: plain channels, lipped channels, double-fold (return) lipped channels, web-stiffened lipped channels, web/flange-stiffened lipped channels, lipped zed-sections, hat-sections, rack-sections and I-sections (formed by back-to-back plain channels). The first part of the work is devoted to plain channel columns and starts with a parametric study aimed at gathering failure loads of columns with continuously varying geometries and yield stresses, so that they (i) buckle in either major-axis flexural-torsional or minor-axis flexural modes and (ii) cover a wide slenderness range. These failure loads are then used to assess the quality of their predictions yielded by the codified global DSM design and to propose modifications to improve this quality. The second part of the work employs the modified DSM-based global design curves, as well as the current one, to predict a fairly large number of numerical failure loads of columns exhibiting the remaining eight cross-section shapes. This extensive parametric study shows that the failure load predictions provided by the proposed/modified DSM global strength curves (i) have very high quality and, for the columns considered, (ii) clearly outperform those yielded by the current design curve. In addition, the advantages and disadvantages of the proposed DSM global design curves are also discussed.

ABSTRACT: The force-displacement curve of circular tubes under lateral crushing load is typically divided into three stages. However, the plateau force actually shows a linearly increasing trend under compression load. As a matter of fact, a stable plateau force is remarkably important for the energy absorption devices. In an effort to overcome this drawback, this paper proposes an internally nested energy absorption system consisting of a circular tube and an elliptical tube, and it is promising to replace the single circular tube as the dominated impact protective structure in the helicopter seats. The experimental investigations of the circular tubes, the elliptical tubes and the nested circular-elliptical tube system (CETS) are carried out to study the mechanical behaviors of the tubes subjected to the lateral crushing load. In addition, an analytical model for the CETS is established on the basis of the rigid-perfectly plastic material model. The results indicate that the plateau force of the circular-elliptical tube system is extremely stable while the single circular or elliptical tubes has the plateau forces linearly increasing or decreasing. Besides, the 3D finite element model of the nested tube system is developed through LS-DYNA, and it is also validated by comparison with the experimental result of the CETS. Based on the numerical simulations, a parametric investigation is conducted to understand the effect of
the internal radius of the circular tube, the ovality of the elliptical tube, the number of elliptical tube and the impact velocity on the mechanical response and crashworthiness characteristics for the CETS.

Miguel Ormeno, Tam Larkin and Nawawi Chouw (Department of Civil and Environmental Engineering, Faculty of Engineering, the University of Auckland, New Zealand), “Experimental study of the effect of a flexible base on the seismic response of a liquid storage tank”, Thin-Walled Structures, Vol. 139, pp 343-346, June 2019, https://doi.org/10.1016/j.tws.2019.03.013

ABSTRACT: Previous studies have demonstrated that strong earthquakes can cause severe damage to storage tanks. In many countries tanks are built near the coast on soft soils. Because of the difference in stiffness between the tank (rigid) and the soil (flexible), the soft soil causes an elongation in the period of the impulsive mode of the soil-foundation-tank system and, therefore, this flexible base can have an important effect on the seismic response. Numerical studies by other researchers have shown the influence of a flexible base on the seismic response of storage tanks. However, experimental investigation on the effects of a flexible base using sand box on the key design parameter, i.e. stress developed in the tank shell, has not been reported. In this research shake table experiments were performed. Sand in a box is used to simulate the flexible base. Actual earthquake records scaled to the New Zealand design spectrum for Wellington City are used. The results showed that in comparison with the rigid base case (model placed directly on the shake table) the axial compressive stresses decreased. The experimental results are corroborated by a numerical model.

ABSTRACT: A generalized theory is formulated for the analysis of thin shells of general curvatures based on the variational form of the Hamiltonian functional in conjunction with tensor calculus. Simplifying approximations and subtle inconsistencies made at the early stages of common classical formulations are avoided herein, and hence, the present treatment leads to field equations and boundary conditions that are accurate and consistent. The theory is then specialized to circular cylindrical shells. The well-known field equations of Flugge and Donnell-Mushtari-Vlasov (DMV) theories are recovered as consistent approximations from the present theory. Closed form solutions are then developed for the present and past cylindrical shell theories by Flugge, Timoshenko, and DMV. A comparative study is conducted to assess and quantify the effects of approximations made in classical theories on the predicted displacements and stresses.

ABSTRACT: This study reports the formulation of a realistic aircraft wing model based on thin-walled composite beam theory. In this model, NACA 4-digit-series airfoils were selected for the wing-section. The circumferentially asymmetric stiffness lay-up was implemented and two different sets of coupling systems corresponding to the proposed model were utilized. The eigenvalue problem was solved by the extended Galerkin method and the natural frequencies were computed as a function of the ply angle. The results of the free vibration analysis along with the governing system of the proposed model contributes to the theory of anisotropic thin-walled beams, emphasizing the importance of thin-walled structures in the design of advanced aeronautical structures.

ABSTRACT: This paper presents a novel technique for the nonlinear dynamic instability analysis of graphene-reinforced composite (GRC) laminated plates resting on an elastic foundation and in thermal environments. The GRC layers are arranged in a piece-wise functionally graded (FG) pattern along the plate thickness direction and each layer of the plate contains different volume fractions of graphene reinforcement. The material properties of a GRC layer are assumed to be temperature-dependent and are estimated by the extended Halpin–
Tsai micromechanical model. The governing equations are based on a higher-order shear deformation plate theory with the geometric nonlinearity being defined by the von Kármán strain-displacement relationships. The plate-foundation interaction and thermal effects are also included. The novelty of this study is that the motion equation and the postbuckling equilibrium equation are derived by a two-step perturbation technique and are then solved simultaneously to determine the dynamic in-plane load and frequency uniquely for a given plate amplitude. The numerical illustrations reveal the nonlinear dynamic instability responses of FG-GRC laminated plates under different sets of thermal environmental conditions, from which results for uniformly distributed (UD) GRC laminated plates are obtained as comparators.

ABSTRACT: This work studies the nonlinear post-instability responses of in-plane bi-directional functionally graded (FG) simply-supported and clamped thin panels. The post-flutter responses of panels subjected to a supersonic airflow are considered as the dynamic case and the post-buckling responses as the static case. The effect of thermal and mechanical in-plane loadings on the panels’ stability and post-instability is analyzed. The first-order piston theory is used for the aerodynamic modeling and the classical plate theory (CPT) along with the nonlinear von-Karman’s strains for the structural modeling. The finite element method (FEM) is used for the analysis. The responses of the functionally graded panels are compared to those of the homogeneous panels. Magnesium reinforced by Silicon Carbide nanoparticles composite is considered in this work because of its high stiffness to weight ratio giving it a great potential for aerospace applications. The high stiffening effect of the nano-reinforcements allows the multi-dimensional material grading to maximize the panels’ performance using the minimum amount of the nano-reinforcement.

ABSTRACT: A unified semi-analytical method is presented to study free and forced vibrations of arbitrary shells of revolution stiffened by rings with T cross-section. Combined shells of revolution and rings with rectangular and L cross-sections are included in the titled structure. The ring-stiffened shell is firstly decomposed to several shell segments and rings with T cross-section according to intersections between the shell and rings, and shell segments are further divided into some narrower segments to be treated as conical shells. Rings with T cross-section are modeled as two cylindrical shells (left and right flanges) and one annular plate (web), rather than conventional curved beams. Conical segments, cylindrical segments and annular plates are uniformly analyzed by employing Flügge thin shell theory and expanding displacements as power series. To consider both classic and elastic boundary conditions, the artificial spring technology is employed to restrain displacements at edges. Then, boundary conditions at two edges and a set of continuity conditions of adjacent segments are assembled to the final governing equation. Through comparing free and forced vibration results of present method with the ones in the literature and calculated by finite element method, rapid convergence and high accuracy are demonstrated. Furthermore, effects of elastic boundary conditions and rings are discussed. Results reveal that mode shapes of shells are significantly affected by rings with T cross-section, and in-plane and out-plane deformations of the web of rings cannot be neglected, especially for rings with large height.

ABSTRACT: Thin-walled structural members have complex behavior. It is usual to interpret the complex behavior as the superposition of simpler behavior components, like global, distortional, local, in-plane shear and transverse extension. When the standard shell finite element method is employed for the analysis, the behavior components are not separated, and the results can be difficult to interpret due to the complexity of the deformations. The results are more meaningful if identified, i.e., if the participations of the behavior components are quantified. Methods for the formal identification of the deformations have already been
proposed, by using either the modes of generalized beam theory, or the basis functions of the constrained finite strip method. In this paper a newer and more general method, the constrained finite element method is used. Since this method can handle a wide range of thin-walled members, including members with holes, or members with varying cross-sections, or even stiffened plates, the identification can readily be applied to various thin-walled members. In the paper some particularities of the identification method are highlighted, as well as several sample examples are presented and discussed.

ABSTRACT: Cold-formed steel sections are used in many different shapes based on their applications. Recently, a new C-section known as SupaCee was introduced in Australia with higher flexural capacities compared to traditional channel sections. However, all cold-formed steel sections are vulnerable to web crippling failures due to their higher plate slenderness. Australian/New Zealand (AS/NZS 4600) and North American (AISI S100) Standards use a unified web crippling design equation with four coefficients while Eurocode 3 Part 1.3 uses different design equations to predict the web crippling capacities of cold-formed steel sections. The web crippling coefficients were developed based on the experimental studies undertaken since the 1940s. These experimental studies utilised different test set-ups and specimens lengths and hence the accuracy of predictions using these coefficients may be inadequate. No coefficients are available for unliped channel sections with fastened supports and high strength SupaCee sections while the same coefficients are used for lipped channels with fastened and unfastened supports. To address these shortcomings, the web crippling behaviour of unliped and lipped channel and SupaCee sections was experimentally investigated based on recently developed AISI S909 web crippling test guidelines. Finite element analyses were then performed to extend the range of cold-formed steel sections. Using the web crippling capacity results from both experiments and finite element analyses, new equations were proposed to determine the web crippling capacities of lipped and unliped channel and SupaCee sections. Suitable direct strength method based web crippling design equations were also developed. This paper presents the important details of several detailed web crippling studies undertaken recently including a suite of web crippling design equations that can be adopted in relevant cold-formed steel standards.

ABSTRACT: Cold-formed steel (CFS) built-up members are formed by connecting several single members by fasteners. This paper presents experimental, numerical and analytical studies on the effect of fastener configurations on the flexural rigidity of built-up sections. In this research, two zinc-coated steel C-sections are connected back-to-back to form a double-web built-up I-section, which is subject to weak-axis bending. A closed-formed expression for the flexural rigidity of built-up sections as a function of fastener stiffness, number and position of fasteners, and section geometry is then derived. This is validated against the tests and finite element modelling, and can be adapted more generally to determine the stiffness and global strength of CFS built-up members in bending.

Benjamin W. Schafer (Johns Hopkins University, USA), “Advances in the Direct Strength Method of cold-formed steel design”, Thin-Walled Structures, Vol. 140, pp 533-541, July 2019, https://doi.org/10.1016/j.tws.2019.03.001
ABSTRACT: Twenty years ago, the Direct Strength Method (DSM) was first proposed as an efficient alternative to traditional design methods for thin-walled cold-formed steel (CFS) structural members. DSM may be regarded as one implementation of a class of generalized slenderness methods that are used in structural design. The objective of this paper is to provide additional context on how DSM-based design fits within past design knowledge and summarize the current state of development and future potential of the approach. Although DSM is regarded as a relatively new member design approach, its fundamental principles have long been used to explore relationships between stability, material yielding, and strength. The first ten years of DSM development (1998–2008) focused largely on simple prismatic CFS members under single actions and was conducted by a small group of researchers. In the last ten years of DSM development both the scope of DSM-

ABSTRACT: This paper presents an experimental investigation on the cyclic behaviors of ultra-high performance steel fiber reinforced concrete filled thin-walled steel tubular columns under combined axial compression and cyclic lateral displacement loading. The failure modes, hysteretic behaviors, envelop diagrams, ductile performance, stiffness degradation and energy dissipation capacity were analyzed in detail. Notably, the cyclic behaviors of referenced high strength concrete and normal strength concrete filled thin-walled steel tubular columns were also studied to get a better illustration of the cyclic behaviors of ultra-high-performance steel fiber reinforced concrete filled thin-walled steel tubular columns. Furthermore, the effects of steel tube thickness, axial compression ratio, volume ratio of steel fiber and slenderness on the cyclic behaviors of ultra-high-performance steel fiber reinforced concrete filled thin-walled steel tubular columns were also investigated in detail. The test results indicate that the high strength concrete filled thin-walled steel tubular columns represent a poor cyclic behavior. However, replacing high strength concrete with ultra-high performance steel fiber reinforced concrete to infill thin-walled steel tubes can get an excellent cyclic behavior. Moreover, the cyclic behavior of ultra-high performance steel fiber reinforced concrete filled thin-walled steel tubular columns is also much better than that of normal strength concrete filled thin-walled steel tubular columns.

ABSTRACT: This paper presents finite element investigations on the structural behaviors of circular concrete-filled aluminum tubular (CFAT) stub columns under axial compression. The finite element models are developed by considering the nonlinearities of concrete and aluminum materials and the interactions between the two components. The predicted ultimate strengths, load-axial strain relationships and failure modes are compared to those from collected experimental data. Full range analysis on the load-deformation N-ε are conducted, where the investigations on the multi-axial stress conditions of the aluminum tube and the interaction stress between the aluminum tube and concrete core are included. The verified finite element models are used to carry out a series of parametric studies on key material and geometric properties. The ductility index DI and strain at ultimate strength εu are studied. Equations to determine εu for circular CFAT stub columns are proposed. The applicability of the existing design method for CFST to CFAT stub columns is investigated.

ABSTRACT: The use of bi-tubular structures has gained importance in the design of energy absorption systems for protection of passengers in train collisions. Therefore, it is critical to improve the crashworthiness performance of bi-tubular profiles. For this purpose, the effect of cross-section, bi-tubular clearance and holes as crush initiators is evaluated using finite element simulations. To get reliable outcomes, special emphasis was set on the progressive damage modelling of aluminum 6063-T5 by a Johnson-Cook (J-C) failure model. During
the cross-section study, bi-tubular arrangements based on polygonal and circular cross-section were evaluated by quasi-static compression loads. The results indicate that the circular shapes showed better crashworthiness performance or crush force efficiency (CFE) up to 12.28% respect to a square base structure. A 10.72% improvement in CFE was obtained when the non-dimensionalized clearance between profiles is increased from Lambda=20 to Lambda=40. The effect of holes on crashworthiness performance was evaluated by drilling holes at different locations both in the inner and outer profiles. The results show that the use of holes increased the crush force efficiency and energy absorption (E) capability even more than the effect of clearance alone. Improvements in the order of 2.50% and 12.96% for E, and CFE respectively were computed when holes were placed at the top end of a BC-3 profile with a non-dimensional clearance of Lambda=40. Considering all effects simultaneously, an increase of 24.6% and 26.31% for E, and CFE respectively was calculated. Finally, an application to a crash buffer in a railway transport system is considered. Likewise, its improved crashworthiness behavior is presented.

ABSTRACT: Arch structures made of double corrugated steel sheets, known as K-span, are used as self-supporting building roofs. The cold-rolling method of arch panel production causes the creation of deep-press formed transverse corrugation. The unusual profile shape significantly impedes the use of known design methods. In extreme cases, this might lead to the failure and collapse of K-span structures. This paper presents a method for testing full-size K-span structures using various measuring techniques, and provides a method of numerical analysis of the double corrugated structures. The results of the tests were compared with the results of the numerical analysis to assess the validity of the assumptions made for the calculations. A comparison of the test results and the numerical analyses helped to give practical guidelines for evaluation of the load capacity and stability of double corrugated K-span structures.

ABSTRACT: The multistable elastic behavior of a shallow dome with a cosine-curved profile is investigated in this work. The dome exhibits snap-through instability and could be used as a building block for energy dissipation mechanism in structures subjected to cyclic loading and high deformation demands. Numerical and experimental studies were carried on the geometric and material properties of the cosine-curved domes (CCD) under concentrated load at the apex. Finite element analyses (FEA), validated by experimental tests on 3D printed specimens, were conducted to study the controlling geometric and material properties of the CCD. Three types of response were recognized and discussed based on the force- and strain energy-displacement curves. Limitations on the geometric parameters that govern the recoverability of the original shape and the stability state upon load removal are also identified. In addition, empirical relations to estimate the limit-point load and displacement, and to characterize the snap-through response were developed. Good agreement was observed using the determined limits on the geometric parameters and the developed relations with the results from FEA and experimental tests.

ABSTRACT: The paper presents a general theoretical framework to investigate the dynamic behavior of rotating doubly-curved shell structures made of Functionally Graded Materials (FGMs). A clear advancement of the present formulation is the possibility to apply a rotating speed (angular velocity) about a general axis of the global reference system. It is important to underline that this aspect is innovative with respect to the previous studies proposed in the literature, in which the angular velocity is only applied about the revolution axis the shell. Furthermore, several Higher-order Shear Deformation Theories (HSDTs) are used to investigate the problem at issue. The results of various numerical applications are presented to discuss the effect of the choice of the axis of rotation, as well as the geometric features of the shells, on the dynamic response of the structures.
In particular, the analyses are performed to evaluate the critical value of rotating speed, which define the stiffness reduction of the structure. A five-parameter power law is developed to define the variation of the mechanical properties of the FGMs along the thickness of the structures. The accuracy of the current formulation, which includes the effects of both Coriolis and centripetal accelerations, is verified by means of the comparison with the results available in the literature. The solutions are carried out numerically by means of an efficient tool that allows to solve the strong formulation of the governing equations.

ABSTRACT: In recent years, externally bonded fibre reinforced polymer (FRP) material has gained popularity as an efficient means of strengthening existing civil engineering infrastructure. In the case of steel structures, FRP has frequently been deployed to strengthen against static and fatigue loads. However, the understanding of the effect of impact load on strengthened structures is still in its early stages. In parallel with this, most of the existing studies on impact have concentrated on small scale elements. Thus, the study presented here is aimed at examining the effectiveness of carbon fibre reinforced polymer (CFRP) in strengthening full-scale steel I-section columns against impact load. To achieve this aim, a non-linear finite element model built using ABAQUS was validated against experimental tests and then used to simulate the strengthening technique. The model included failure criteria of all investigated materials (steel, CFRP and adhesive material). Various parameters including boundary conditions, preloading level, kinetic energy, impact location and impact direction were examined. The CFRP strengthening technique was found to be highly effective in preventing column failure whether by global buckling failure or transverse shear failure. In addition the strengthened columns exhibited a reduced axial and transverse displacement by more than 70% in many cases.

Feng Zhou and Ben Young (First author is from: State Key Laboratory of Disaster Reduction in Civil Engineering, Tongji University, Shanghai, 200092, China), “Experimental investigation of concrete-filled single-skin and double-skin steel oval hollow section stub columns”, Thin-Walled Structures, Vol. 140, pp 157-167, July 2019, https://doi.org/10.1016/j.tws.2019.03.036

ABSTRACT: Both concrete-filled single-skin and double-skin steel tubular stub columns were investigated experimentally in this study. The skin of the composite columns was constructed using steel oval hollow section (OHS) tubes. A series of tests was performed to investigate the effects of the geometric dimension of steel OHS tube and concrete strength on the behaviour and strength of composite columns. The overall width-to-thickness ratio of the OHS tube sections ranged from 15.8 to 62.6. The structural performance of the composite columns was investigated using different nominal concrete cylinder strengths of 40, 70 and 100 MPa. The composite column lengths were chosen so that the length-to-width ratio generally remained at a constant value of 3 to prevent overall column buckling. The concrete-filled OHS tube specimens were subjected to uniform axial compression. The test strengths, load-axial shortening relationship and failure modes of the composite columns were presented in this paper. The test strengths were compared with the design strengths calculated using the American Specification and European Code for composite steel and concrete structures. It was shown that the design strengths do not agree well with the experimental results.

ABSTRACT: This paper presented axial compression tests on the behavior of the circular concrete filled steel tube stub columns with double inner square steel tubes (DIS-CFST). A total of 27 DIS-CFST stub columns with different eccentricity ratio (e), hollow area ratio (ψ) and concrete compressive strength (C) were tested. The study mainly investigated the failure modes, ultimate bearing capacity, load-strain curves, load-displacement curves, initial stiffness at elastic stage (k) and ductility of the DIS-CFST stub column. The failure mode of DIS-CFST stub columns observed from the tests was local buckling and no crack was observed on the surface of the specimens. It was found that concrete compressive strength had remarkable influence on ductility and ultimate
bearing capacity of DIS-CFST stub columns. However, eccentricity ratio had little influence on the behavior of DIS-CFST stub columns. Experimental results showed that when the hollow ratio was small, it had little effect on the ultimate load-carrying capacity of DIS-CFST stub columns. However, the ultimate bearing capacity of specimens significantly decreased when hollow area ratio was large. The eccentricity ratio, hollow area ratio and the concrete compressive strength had slight influence on initial stiffness at elastic stage. Furthermore, the ductility of DIS-CFST stub columns increased with the decrease of hollow area ratio. A simplified formula was proposed to calculate the ultimate bearing capacity of DIS-CFST stub columns. The predicted ultimate bearing capacities were in good agreement with DIS-CFST stub column test results. By comparing with the existing strength calculation formula, it can be concluded that the ACI code, EC4 and Han's method were more satisfied with the requirements of the design.

ABSTRACT: The thermoelastic response of aerospace structures is significantly influenced by structural nonlinearities and conventional design tools based on assumption of linearity prove to be insufficient. A nonlinear analysis of the thermoelastic response of aerospace structures opens up the possibility to capture the rich bifurcation behaviour of such panels. The primary objective of this paper is to study the impact of non-linearity and local geometric features, particularly corrugations, on the thermoelastic response and bifurcation characteristics of a hat-stiffened panel. The study derives its motivation from the SR-71 Blackbird that was designed with corrugations in the upper and lower wing skins. A representative hat-stiffened panel is created with corrugations on the skin face-sheet and stiffeners, similar to those on the SR-71 skin panels. The amplitude of these corrugations is varied and the panels are loaded till the bifurcation point is reached. The results show that in the absence of corrugations (at face-sheets) the panel experiences two bifurcation points. The first is similar to the bifurcation predicted from a typical linearized buckling analysis and is surrounded by stable equilibrium branches such that a small perturbation causes the panel to switch to this branch. The second bifurcation point is surrounded by unstable subcritical branches and a perturbation can cause violent snap-through. Adding a face-sheet corrugation causes the first bifurcation point to disappear and the temperature for the second bifurcation point to increase monotonically with the amplitude of corrugation. The displacement and stress at the panel mid-point for a given temperature also reduces with increasing corrugation amplitude. The corrugation in stiffeners does not provide any tangible benefit within the scope of this study.

ABSTRACT: The shear lag effect can significantly affect the performance of wide-box structures, and even becomes one of the most important influencing factors endangering structural safety. This paper develops a theoretical analysis method, which is designated as PM analysis for analyzing shear lag phenomenon in thin-walled box-section beam with arbitrary width of cantilever flange. In this method, the introduction of initial shear rotation (or initial shear strain) γ, due to the effect of web restraint on flanges, is innovatively proposed and further employed in describing the additional warping displacement in top lateral cantilever flanges, and a practical and straightforward procedure of coefficient α is designed (DP) based on the proposed assumptions. In addition, a modified method to PM-DP analysis is developed for improving the defects of the hypothesis of shear-lag warping displacements in top lateral cantilever flanges, that is, PM-DP(M) analysis. The differential equations for generalized displacement ω(x) and the standard magnitude of shear-lag warping displacement U(x) of the beam are deduced by means of the principle of minimum potential energy (MPE) and solved with the given boundary conditions. Numerous models of thin-walled box-section with arbitrary width of top lateral cantilever flanges under distributed load are chosen and built through a software program (ABAQUS). The results obtained from PM analysis (PM-LB, PM-DP and PM-DP(M)) are summarized into a series of curves indicating the distribution of normal stress and the displacements for various examples, and compared to those obtained from the finite element method (FEM). The study widely demonstrates the strong applicability and high precision of PM-DP(M) analysis, which can be considered as an ideal solution in predicting shear lag.
effect for thin-walled box-section beam with arbitrary width of cantilever flange and, possibly, be adopted as valuable reference for the design of related thin-walled structures.

ABSTRACT: This paper presents an analytical and numerical investigation of the relationship between the compressive load level and the natural frequency variation toward a vibration correlation technique for the buckling load calculation of imperfection-sensitive isotropic cylindrical shell structures. Firstly, a back-to-basic study is proposed and the linear equation between the applied load and the square of the loaded natural frequency is revisited. Such review considers the Flügge-Lur'e-Byrne's linear shell theory for the free vibrations of an isotropic unstiffened cylindrical shell under uniform axial loading. The demonstrated linear equation is rearranged for expressing the square of the applied load as a quadratic function of the square of the loaded natural frequency. The suggested formulation provides the analytical support to a novel vibration correlation technique that has been empirically proposed and experimentally validated for unstiffened cylindrical shells. Aiming a numerical verification based on finite element models, two cylindrical shells are defined. At first, the critical buckling load and the fundamental natural frequency for different load levels are determined and compared to the analytical results for validation of the numerical models. The finite element models are extended considering geometric nonlinearities, more realistic boundary conditions and three magnitudes of a benchmark measured initial geometric imperfection. The numerical results are considered for analyzing the variation of the natural frequency in the surroundings of buckling and for verifying the vibration correlation technique.

ABSTRACT: The shear stability of steel webs near the support section for long-span composite girders with corrugated steel webs is one of the main control factors for structural safety, which should be paid special attention to. Generally, concrete is poured on the inner side of corrugated steel webs to improve its shear stability, but encased concrete increases the weight of the girder, raises the difficulty of the construction process, and reduces the efficiency of the prestressing application. This paper proposes a new type of stiffened corrugated steel webs at the support area by adopting vertical or/and horizontal stiffeners instead of encased concrete. In order to explore the shear performance of proposed stiffened corrugated steel webs, experimental and numerical investigations were carried out in the present paper and the companion paper [1], respectively. Four steel I-girders with corrugated webs considering different stiffener arrangements were designed and tested under shear loading. The failure modes, shear strength and stiffness, strain distributions were obtained and analyzed in detail. The test results show that all specimens failed due to interactive shear buckling of corrugated steel web; shear buckling occurred between horizontal stiffeners and bottom flange for horizontal stiffened corrugated steel webs, but extended to the entire height for vertical stiffened corrugated steel webs, the stiffeners distorted associated with the deformation of corrugated steel web. Shear strength of corrugated steel webs can be improved by vertical and horizontal stiffeners. The vertical stiffeners do not affect the “accordion effect” of corrugated steel webs, but the horizontal stiffeners increase the axial stiffness of corrugated steel web in local area and resist bending moment together with top and bottom flanges. The shear strain of stiffened corrugated steel web still distributes uniformly along the height of the web. All the experimental results are then employed in the companion paper for the validation of finite element method and the evaluation of existing analytical models for predicting shear strength of un-stiffened and stiffened corrugated steel webs.

Jia-Bao Yan, Zhe Wang and Jian Xie (School of Civil Engineering/Key Laboratory of Coast Civil Structure Safety of Ministry of Education, Tianjin University, Tianjin, 300350, China), “Compressive behaviours of double skin composite walls at low temperatures relevant to the arctic environment”, Thin-Walled Structures, Vol. 140, pp 294-303, July 2019, https://doi.org/10.1016/j.tws.2019.03.047
ABSTRACT: Double skin composite (DSC) ice-resistant walls have been proposed for the Arctic oil platforms. This paper makes efforts to study the compressive behaviours of DSC walls at low temperatures of \(-80^\circ\text{C}–20^\circ\text{C}\). Seven DSC walls were tested at low temperatures to investigate the influences of different parameters on their compressive behaviours that included low temperature levels, thickness of steel faceplate, and spacing of connectors. The compressive behaviours of the DSC wall at low temperatures were reported and discussed in terms of failure mode, compressive force versus shortening behaviours, and load-strain behaviours. The influences of different parameters on compressive behaviours of DSC walls at low temperatures were reported and analysed. Theoretical models were developed to predict the ultimate compressive resistance of DSC walls at low temperatures. The accuracy of the developed theoretical models were checked through validations against reported seven test results.

ABSTRACT: Present manuscript is mainly arranged to take into consider the influences of nanofillers' aggregation, beam's shear deformation and various boundary conditions on the vibration frequency of multi-scale hybrid nanocomposites in the framework of finite element based Rayleigh-Ritz method. The constituent material is made from three phases, namely polymer matrix, macro-scale carbon fibers and nano-scale carbon nanotubes. Homogenization procedure is procured based on Eshelby-Mori-Tanaka approach incorporated with a micromechanical scheme to obtain the effective material properties via a two-step method. In addition, a new refined higher-order beam theory is introduced to govern shear stress and strain through the thickness direction. Furthermore, influences of different boundary conditions are included, too. The accuracy of the presented finite element formulations is examined by setting a comparison between the dimensionless frequency of multi-scale hybrid nanocomposite beams via both analytical and finite element solutions. Afterwards, parametric studies are adopted to put emphasize on the influence of various terms on the vibrational behaviors of nanocomposite beams. It is reported that influence of different parameters deeply depends on the magnitude of volume fraction of nanofillers inside the inclusions.

Mao Yang, Bin Han, Peng-Bo Su, Zi-Han Wei, Qi Zhang, Qian-Cheng Zhang and Tian Jian Lu (First author is from: State Key Laboratory for Mechanical Structure Strength and Vibration, Xi'an Jiaotong University, Xi'an, 710049, PR China), “Axial crushing of ultralight all-metallic truncated conical sandwich shells with corrugated cores”, Thin-Walled Structures, Vol. 140, pp 318-330, July 2019, https://doi.org/10.1016/j.tws.2019.03.048

ABSTRACT: Novel ultralight all-metallic truncated conical sandwich shells (TCSS) with corrugated cores are designed and fabricated using the molding process. Quasi-static axial compression tests are performed to investigate the crushing behaviors of the proposed structure, with focus placed upon its peak strength and energy absorption capacity as well as the interaction effect of its face-sheets and corrugated core during the crushing process. Detailed parametric study with three-dimensional finite element simulations is subsequently carried out to further explore the failure mechanisms as well as the influence of key geometrical parameters. Finally, the response surface models of specific energy absorption (SEA) and peak force (PF) are established with key design variables, and the Pareto fronts in terms of maximum SEA and minimum PF are obtained. Relative to monolithic conical shells having equal mass, the SEA of the TCSS is significantly greater while the PF is smaller, attractive for energy absorption applications demanding high levels of crashworthiness.

ABSTRACT: Recently, advanced materials whose properties vary within a continuous pattern have been put to use to design and manufacture modern structures. In the current investigation, size dependencies are captured in the nonlinear free vibration characteristics of micro/nano-beams made of bi-directional functionally graded materials (2D-FGM). With the aid of the nonlocal strain gradient elasticity theory and the variational principle, the size-dependent nonlinear differential equations of motion are derived within the framework of the refined
hyperbolic shear deformation beam theory. It is supposed that the material properties are distributed exponentially along longitudinal direction, and vary based on the power law function in lateral direction. Moreover, the deviation of the associated physical neutral plane from the mid-plane counterpart is taken into consideration. By employing a numerical solution methodology on the basis of the generalized differential quadrature method (GDQM) together with Galerkin technique and pseudo arc-length continuation method, the nonlocal strain gradient frequency-deflection responses of 2D-FGM micro/nano-beam are obtained corresponding to various values of longitudinal and lateral material property indexes and small scale parameters. It is revealed that the increment made by the strain gradient size dependency in the value of the nonlinear frequency is more than the reduction caused by the nonlocality, especially for the lower maximum deflection imposed to the 2D-FGM micro/nano-beam. Also, it is indicated that for lower values of the material property gradient indexes, the reduction in the nonlinear frequency caused by the lateral functionally graded pattern in the absence of the axial functionally graded pattern is more than that made by the vice versa case. However, for higher values of the material property gradient indexes, an opposite observation is seen.

ABSTRACT: In this paper, performance of the smart constrained layer damping (SCLD) treatment with elliptical geometrical plan form is investigated for controlling the vibrations of various types of doubly curved composite shells. The SCLD treatment is composed of a viscoelastic layer and an advanced constraining piezoelectric composite (PZC) layer attached at the top surface of the composite shell. A mesh free (MF) model of the smart composite shell has been developed based on the element free Galerkin approach to study its dynamic behaviour within the framework of a mixed layerwise displacement field theory considering transverse extensibility. Spherical, paraboloid and hyperboloid type composite shells with antisymmetric/symmetric cross-ply as well as general angle-ply lamination sequences are considered for the analysis. The numerical results demonstrated that the elliptical SCLD patches are more efficient in attenuating the vibration of the spherical and paraboloid laminated shells while the regular rectangular/square plan form patches are effective for the hyperboloid shells. The numerical results also indicate that the elliptical patches are having higher performance index in enhancing the active damping characteristics of the composite shells. Investigations are also carried out to analyze the effect of the variation in orientation of the piezoelectric fibers in the active PZC layers in attenuating the vibration of shells.

Wanxin Li, Xiyue An, Qing Zheng, Fan Yang and Hualin Fan (First author is from: Research Center of Lightweight Structures and Intelligent Manufacturing, State Key Laboratory of Mechanics and Control of Mechanical Structures, Nanjing University of Aeronautics and Astronautics, Nanjing, 210016, China), “Hierarchical design, manufacture and crushing behaviors of CFRP tubular energy absorbers”, Thin-Walled Structures, Vol. 140, pp 416-425, July 2019, https://doi.org/10.1016/j.tws.2019.03.058

ABSTRACT: Hierarchical topology is introduced to construct weight-efficient carbon fiber reinforced polymer (CFRP) tubular energy absorbers through filling small-diameter tubes into large-sized tubes. Crushing behaviors of the thin-walled tubes and the hierarchical tubes are investigated through quasi-static compression experiments and compared with each other. Large-diameter and long thin-walled tubes always fail at brittle modes with limited energy absorption (EA). The hierarchical tubes are crushed progressively and have excellent EA, for the mean crushing force (MCF) exceeds half of the peak force (PF) and the crushing distance is larger than half of the tube length. The improvement in the EA is attributed to the interactions among substructures at different levels which induce a ductile crushing mode. Taking into account the priority of low density, the hierarchical CFRP tubes are weight-efficient absorbers.

ABSTRACT: This study presents an effort to clarify the effects of initial geometric distortions to the buckling capacity of stiffened panels through numerical experimentation. Four types of imperfections have been
considered, that is local (plate, web and stiffener) and global distortion types (column-like). These discrete types were considered as the factors that tend to affect the buckling capacity of the adopted finite element model. Statistical techniques of Design Of Experiments have been applied. A One Factor At a Time analysis along with a full factorial analysis have been performed for screening purposes, and the significant main and interaction effects have been evaluated. The Response Surface Method was finally employed so as to verify and narrow down the number of significant factors. From the four distortion types examined and for the particular involved collapse modes in the evaluated geometries, it was concluded that when the stiffened panel involves global distortion such that maximum global bending stress develops at the plate, then only local plate and web distortions are significant, while stiffener and global distortion may be neglected from the analysis. On the other hand, when global distortion maximizes the global bending stress at the stiffener top, then local web and this particular global distortion type have to be included.

ABSTRACT: Auxetic chiral structures consisting of circular ring nodes and tangentially connected ligaments are engineered systems that exhibit excellent flexibility, vibration attenuation, impact resistance performances. In this paper, the out-of-plane dynamic crash behaviors of anti-tetrachiral, hexachiral and hierarchical chiral structures are studied. The energy absorption efficiency, plateau stress, peak stress of chiral structures with different ligament length, node radius, ligament thickness, and level of structural hierarchy under different external crashing conditions are compared, and identical mass per area of different unit cell configurations are assumed. It is found that anti-tetrachiral structure is able to generate higher plateau stress and better energy absorption efficiency than hexachiral structures. Making use of the mechanical benefits of structural hierarchy, novel hierarchical chiral structures are proposed for improving the crash energy absorption abilities of chiral structures, and relations between crash energy absorption performances and unit cell geometries are explored, such as: energy absorption efficiency, plateau stress of chiral structures. Based on systematical analysis, optimized chiral and hierarchical chiral cellular structure can be designed for impact energy absorption in protective sandwich structures.

ABSTRACT: The material properties of aluminium alloys could be affected significantly as temperature rises. The present study aims to investigate the behaviour of aluminium alloy beams at elevated temperatures using finite element analyses. The newly developed numerical model was validated against a total of eight square hollow section beams subjected to three-point bending tests at elevated temperatures. The validated model was used to generate 120 numerical results in the parametric study. Three key parameters were considered, including cross-section slenderness ranging from 8 to 38, temperatures ranging from 24°C to 600°C and two aluminium alloys (6061-T6 and 6063-T5). Thus, a data pool containing a total of 128 experimental and numerical results was formed. The appropriateness of the design rules in the American Aluminium Design Manual, the Australian/New Zealand Standard, Eurocode 9 and the continuous strength method (CSM) for aluminium alloy beams at elevated temperature are assessed against the newly generated data pool. In comparison, the design strengths predicted by the four design methods are generally conservative, whereas the CSM approach is found to be the most accurate and consistent throughout the full temperature range. Additionally, reliability analysis has also been conducted to evaluate the reliability level of the aforementioned design methods for aluminium alloy beams at elevated temperatures.

Mishra and Kaan Inal (Primarily from: Department of Mechanical and Mechatronics Engineering, University of Waterloo, Waterloo, Canada N2L 3G1), “A computational mechanics engineering framework for predicting the axial crush response of aluminum
extrusions”, Thin-Walled Structures, Vol. 140, pp 516-532, July 2019, 
https://doi.org/10.1016/j.tws.2019.02.007
ABSTRACT: Automakers are developing new lightweight aluminum alloys for automotive structures to reduce vehicle weight. However, these alloys require extensive mechanical characterization for accurate calibration of a numerical model, which is often a painstaking task. Automakers are exploring alternative strategies to reduce the number of experiments required for characterizing these new alloys without sacrificing accuracy in predicting performance. The method of virtual experimentation through computational mechanics engineering (CME) with crystal plasticity is showing promise in satisfying this need. This work presents a CME framework for predicting the axial crush behavior of an aluminum alloy AA6060-T6 extrusion using only a single uniaxial stress-strain response and 2D electron backscatter diffraction (EBSD) scans. An anisotropic phenomenological model is generated using a 3D reconstructed microstructure and a calibrated crystal plasticity model. Additional mechanical characterization is performed to qualify the proposed CME framework. Finite element simulations that employ the CME framework are performed to evaluate the suitability of this methodology in quasi-static axial crush applications. Quasi-static axial crush experiments of the extrusion are performed to validate the finite element simulations and the CME framework. Simulations using the CME framework were capable of predicting the experimental crush response with 3–4%. The proposed CME framework can help automakers reduce the number of experiments needed for the development of components in large deformation, such as crush.

Baotong Li, Congjia Huang, Chengbin Xuan and Xin Liu (Primarily from: Key Laboratory of Education Ministry for Modern Design & Rotor-Bearing System, Xi’an Jiaotong University, Xi’an, 710049, PR China), “Dynamic stiffness design of plate/shell structures using explicit topology optimization”, Thin-Walled Structures, Vol. 140, pp 542-564, July 2019, https://doi.org/10.1016/j.tws.2019.03.053
ABSTRACT: The aim of this article is to present a novel and viable topological design approach for minimizing dynamic compliance of stiffened plate/shell structures subjected to time-harmonic loading with prescribed excitation frequency. In this method, the generalized incremental frequency technique (GIF) is introduced to transform the optimization problem into several sub-problems by making the prescribed excitation frequency located within different sub-intervals constructed by adjacent resonance frequencies. Based on this, a set of local optimum designs are identified by associating with the smallest value of dynamic compliance in each sub-interval, and then the optimized solution is selected from among these candidate solutions. Furthermore, the GIF technique is integrated into a Lagrangian-based topology optimization framework, where the stiffening topologies are represented explicitly by a set of geometric primitives such as line segments. In order to get an optimal layout solution, a special interpolation scheme called stiffness and mass transformation approach (SMTA) is presented to separate the line segments from the underlying FEM grids, so that they can move freely within the design domain. To demonstrate the benefits this method affords for dynamic design problems, three numerical examples are validated in detail. In each of the cases the optimization enables a significant reduction in the dynamic compliance. The proposed method allows for more flexibility in topology optimization, which is applicable for large-scale practical dynamic design problems.

ABSTRACT: Structural design rules for prestressed cold-formed steel beams, considering both the prestressing and imposed vertical loading stages, are presented herein. In the proposed approach, the cold-formed steel member is designed as a beam-column using linear interaction equations in conjunction with the Direct Strength Method (DSM), while the prestressed cable is designed by ensuring that its tensile capacity is not violated during the two loading stages. In the present paper, the design approach and the failure criteria, which define the permissible design zone for the prestressed system, are first introduced. The suitability of the design recommendations is then assessed by comparing a set of parametric finite element (FE) results for several combinations of prestress levels, beam geometries and cable sizes, with the corresponding design predictions. Finally, following reliability analysis, the implementation of the design recommendations is illustrated through a practical worked example.

ABSTRACT: Double skin composite (DSC) ice-resistant walls have been proposed for the Arctic oil platforms. This paper makes efforts to study the compressive behaviours of DSC walls at low temperatures of −80 °C−20 °C. Seven DSC walls were tested at low temperatures to investigate the influences of different parameters on their compressive behaviours that included low temperature levels, thickness of steel faceplate, and spacing of connectors. The compressive behaviours of the DSC wall at low temperatures were reported and discussed in terms of failure mode, compressive force versus shortening behaviours, and load-strain behaviours. The influences of different parameters on compressive behaviours of DSC walls at low temperatures were reported and analysed. Theoretical models were developed to predict the ultimate compressive resistance of DSC walls at low temperatures. The accuracy of the developed theoretical models were checked through validations against reported seven test results.

ABSTRACT: An efficient modelling technique based on one dimensional (1D) beam finite element analysis for buckling of thin-walled laminated composite beams having open/closed sections is proposed. The formulation derived has sufficient generality for accommodating arbitrary stacking sequences of the individual beam section walls, and includes all possible couplings between axial, shear, bending and torsional modes of deformation. The effects of transverse shear deformation of the section walls and out-of-plane warping of the beam section are considered where provision exists to restrain or allow warping deformation. The incorporation of shear deformation leads to a problem in the finite element implementation of the proposed beam kinematics, but this is successfully addressed adopting a novel modelling concept. Numerical results obtained for the sample cases of open sections I beams and closed section box beams are presented. The numerical results are benchmarked/compared to data available in open literature, and it is shown that the proposed model performs very well. Finally, a study of the effect of axial and end moment loading, acting alone or in combination, on the buckling response of thin-walled composite beams is presented.

ABSTRACT: For crashworthiness applications, hollow composite tubes have been proposed and studied as impact-bearing members in earlier studies to replace metal tubes and beams which resisted impact by bending. This study focusses on the effect of the addition of hollow glass microballoons (GMB) in composite tubes for compressive loading. Epoxy containing 0 to 0.3 volume fraction of GMB is used with woven glass fabrics to fabricate the specimens. The mean load and energy absorbed while progressively crushing the tubes are experimentally obtained. The variation of these properties with the addition of GMB is analyzed. It is found that the compression properties improve with the addition of hollow glass particles. To explain the different modes of energy dissipation, the basic mechanical properties of the GMB-filled composites are obtained by various mechanical tests. These results are also used in an energy-based model to predict the properties of the tubes under compression.

ABSTRACT: Novel steel-concrete-steel (SCS) sandwich composite walls with normal weight concrete (NWC) and J-hook connectors have been proposed for shear walls in buildings and protective walls in Arctic offshore platforms. Eight SCS sandwich walls with J-hook connectors and NWC were tested under monotonic compression. Investigated parameters in this testing programme included thickness of steel faceplate, spacing of J-hook connectors, strength of NWC core, and different types of connectors. Based on the reported test results, the influences of these parameters were analysed and discussed. Theoretical models were developed to predict compressive resistance of SCS sandwich walls with different types of connectors. The developed analytical models considered the confinement of steel faceplate on compressive strength of concrete core and proposed new buckling length coefficient for steel faceplate in SCS sandwich wall. The accuracies of the proposed analytical models were checked through validations against 50 test results reported by authors and other researchers. Finally, step-by-step design procedures were proposed to determine compressive resistance of SCS sandwich walls with different types of shear connectors.

ABSTRACT: Current work concentrates on large displacement dynamic analysis of super-elliptic (SE) shells made of functionally graded materials (FGMs) employing generalized differential quadrature (GDQ) technique. SE shells can be in quasi-rectangular, elliptical or cylindrical shell forms according to the parameters in super-ellipse formulation. In this paper, large displacements are considered through Green-Lagrange nonlinear strain-
displacement relationships derived for SE shells with full nonlinearity in transverse shear. Present solution is based on first-order shear deformation theory (FSDT). Virtual work principle and GDQ method are utilized to derive equation of motion and to express spatial derivatives existing in equation of motion, respectively. Newmark average acceleration method is employed in the solution of equation of motion. By solving various FGM super-elliptic (FGM-SE) shell problems, effects of FGM material properties (using different ceramic/metal pairs like Alumina/Steel (Al₂O₃/Steel), Zirconia/Aluminum (ZrO₂/Al), Alumina/Aluminum (Al₂O₃/Al), Zirconia/Monel (ZrO₂/Ni-Cu) and Silicon Nitride/Steel (Si.N./Steel)), SE geometric characteristics (ellipticity and ovality) and boundary conditions on dynamic response are investigated.

ABSTRACT: Concrete-infilled double steel corrugated-plate walls (CDSCWs) are composed of two steel corrugated-plates (SCPs) which are connected through bolts, and concrete filled the spacing formed between the two SCPs. Two vertical boundary elements are installed additionally at both sides of CDSCWs. On the one hand, the corrugated configuration of SCPs has great improvement on the load-bearing efficiency of CDSCWs; on the other hand, much higher bearing capacities and better seismic performance for CDSCWs are provided owing to the interactions among SCPs, bolts and infilled-concrete. This paper investigates the load-bearing mechanism and strength design formulae of CDSCWs under compressions. Since SCPs are prone to local buckling failure between two rows of bolts under the conditions of large vertical bolt spacing and small thickness of SCPs, this paper mainly focuses on the load-bearing mechanism of SCPs in CDSCWs under uniform compressions. The unilateral constraint on SCPs provided from infilled-concrete and the restraining effect on the flexural deformation of SCPs owing to bolts are considered. At first, series of finite element (FE) eigenvalue buckling analyses are conducted to study the elastic buckling behavior of SCPs subjected to uniform compressions. On the basis of Euler's formula, the formulae for predicting the elastic buckling stresses and corresponding normalized slenderness ratios $\lambda$ of SCPs are achieved respectively. The instability performance of SCPs under uniform compressions is then investigated through FE nonlinear analyses, and accordingly the stability coefficient $\phi$ is attained. The corresponding $\phi-\lambda$ curve is therefore established in order to calculate the ultimate bearing capacities of SCPs. In addition, the cooperative performance of material strengths between SCPs and concrete is analyzed numerically when CDSCWs reach their compressive ultimate strength. With this consideration, the design method for predicting the cross-sectional strength of CDSCWs under compressions is proposed. Moreover, a CDSCW specimen with I-section is tested under a compressive load. Its cross-sectional strength is investigated experimentally. The results of the experiment coincide with those of numerical simulation, this verifying the safety and validity of the design method for cross-sectional strength design of CDSCWs.

ABSTRACT: Residual stresses and distortions reduce the performance of welded structures. A lot of mechanisms were developed to minimize its consequences. Although, welding sequences (WSQ) effect in the residual stresses, measured by a portable XRD equipment in standard stiffened panels, were not deeply studied so far. In this paper, three sequences significantly changed the residual stresses, which are generated by the arc welding process due to the effect of the temperature, directly affecting the distortions. As a result a simple and inexpensive modification in the WSQ, the longitudinal and transversal compressive residual stresses were reduced by 59% and 86%, respectively. Distortions were also decreased by 68%. A higher welding velocity (100cm/min) and low heat input (0.64KJ/mm) were obtained by application of robotized FCAW. The results could prove the viability of using the portable XRD analyses in the shipbuilding industry.

ABSTRACT: Fifteen corrugated steel web I–beams were designed to investigate the shear buckling behavior and shear strength of corrugated steel webs with artificial corrosion pits. Different corrosion height, depth, and pit diameter, were considered in the shear loading tests. Critical buckling load and ultimate strength were compared with those calculated by existing formulas. In addition, Failure modes were discussed. Test results showed that corrosion volume decreased by 8% and bearing capacity decreased by nearly half compared with no corrosion. All corrugated steel webs were evenly sheared before the critical load was reached. Before reaching ultimate strength, the curve of vertical displacements and load is linear and the slope was affected by the corrosion. Perforation affected the failure modes of corrugated steel webs. Existing formulas yielded accurate and reliable results for uncorroded corrugated steel webs but cannot be used in the evaluation of the bearing capacity of corroded specimens. Corrosion volume, which was nonlinearly related to bearing capacity, was identified as an important factor that affects bearing capacity. Thus, corrosion volume must be considered in accordance with the actual working situation of corrugated steel webs. Future research should focus on the effect of perforation location and corrosion volume on ultimate strength to develop reliable designs for corrugated steel webs.

ABSTRACT: Compressive stresses present in the knuckle of ellipsoidal heads subjected to internal pressure. The presence of such stresses may make buckling possible. In this study, we combine experimental and numerical methods to investigate the buckling behavior of large-scale thin-walled ellipsoidal heads. Buckling experiments were conducted on three thin large-scale ellipsoidal heads with diameters up to 5m and thicknesses of 5.5mm. Finite element models of the ellipsoidal heads with measured initial shapes were generated to simulate the buckling behavior, which is compatible with the experimental observation that one or more buckles first occur at local positions in the knuckle and more ones form progressively with increasing pressure. Furthermore, the buckles become smaller or even disappear at relatively higher pressure, indicating that buckling is self-limited. These buckling behaviors are explained by changes in compressive stresses and shapes of ellipsoidal heads. In addition, we performed numerical simulation to investigate the effects of material properties, radius-to-height ratio, diameter-to-thickness ratio, and shape imperfection on buckling behavior.

ABSTRACT: Re-entrant anti-trichiral honeycomb is a typical auxetic material. The collapse process can be divided into three stages while its negative Poisson's ratio (NPR) effect under large deformation is still unclear. In the present paper, the NPR effects of re-entrant anti-trichiral honeycombs under large deformation are studied by numerical and theoretical method. Numerical results are verified by the experiments with respect to their deformation mechanism and stress-strain behavior. Theoretical formulas are derived to predict the NPR effect of the honeycomb under large deformation. The analytical predictions are in good agreement with the FEM results. It is revealed that the NPR effect of the honeycomb is magnified with the global strain in the second stage while is weaken in the third stage of the deformation process. The decrease of the ligament-ratio and the mean radius will result in more obvious NPR effect. Variation of cell-wall thickness doesn't have much impact on the Poisson's ratio in the second stage, while smaller cell-wall thickness will induce larger NPR in the third stage. The present work is supposed to shed light on the design and fabrication of re-entrant anti-trichiral honeycombs with desired Poisson's ratio.

ABSTRACT: In this paper, the nonlinear forced vibration of single layered graphene sheet including the pre-Stressed effect is studied based on nonlocal elasticity theory. The graphene sheet is located on a viscoelastic foundation based on Kelvin-Voigt model and exposed to thermo-magnetic-mechanical loads. A particle with constant velocity and concentrated load moves on the graphene sheet and applies mechanical shock to it. At first, using nonlinear strain-displacement relations, the geometrical nonlinearity is modeled. Besides, nonlocal plane theory and Hamilton's principle are utilized for deriving the governing equation. In the second step, using Galerkin method, the partial differential equation is transformed to the ordinary differential equation. Then, governing equation is solved based on multiple time scales method. Finally, frequency-response equations under sub-harmonic and super-harmonic stimulation are studied. Emphasizing the effect of nonlinearity, the results for the nondimensional nonlinear frequency versus nondimensional amplitude, the nondimensional phase angle and nondimensional velocity for single layered graphene sheet are plotted. At the end, numerical results are compared with results in the other researches. The results emphasize that the velocity of the nano particle and force amplitude are responsible to make resonance in the system based on a SLGS. Besides, force amplitude can be effective to intensify the effect of the mechanical shock in behavior of SLGS.

ABSTRACT: The aim of the work is to investigate the low-velocity impact of fully clamped rectangular multilayer sandwich plates with metal foam cores struck transversely by a heavy mass. Analytical models considering interaction of bending and stretching induced by large deflections are developed for the dynamic response of multilayer sandwich plates. Numerical calculations of multilayer sandwich plates under low-velocity impact are conducted and analytical models can capture the numerical results reasonably. The cases of three typical impact locations are considered. Effects of loading location, the multilayer factor and shape of the striker on the structural response are discussed. It is demonstrated that the present analytical model can reasonably predict the low-velocity post-yield behavior of rectangular multilayer sandwich plates with metal foam core struck by a heavy mass.

ABSTRACT: Spectral element method (SEM) is an accurate and efficient frequency domain-based method which has been frequently used in different analyses of various structures. In the present research, for the first time, this method is employed to deal with the wave propagation analysis of moderately thick rectangular plates with two piezoelectric layers attached on the top and bottom surfaces. The equations of motion are derived by taking into account the Mindlin plate theory assumptions and using the Hamilton's principle. The Maxwell's
equation is employed to obtain the governing equation of electric potential in the piezoelectric layers. The differential equations are transformed into the frequency domain by employing the discrete Fourier transform and then a closed-form solution for the Levy type plate attached to piezoelectric layers is introduced. The dynamic stiffness matrix for the smart plate is obtained by applying the exact dynamic shape functions. Accurate and efficient numerical algorithms are introduced to extract the natural frequencies and the dynamic response of the structure under impact loading. The validation of the presented method is accomplished by comparing the obtained natural frequencies and dynamic response with the existing results in the literature and also the results obtained by the Abaqus software. Also, the effects of boundary condition and thickness of the plate and piezoelectric layers on the results are investigated. Independence to the mesh structure and less computational time are the most important advantages of the SEM compared with similar numerical methods like the finite element method.

ABSTRACT: A comprehensive experimental and numerical study of concrete-filled double skin tubular (CFDST) stub columns is presented in this paper. A total of 23 tests was carried out on CFDST specimens with austenitic stainless steel circular hollow section (CHS) outer tubes, high strength steel CHS inner tubes, and three different grades of concrete infill (C40, C80 and C120). The ultimate load, load-deflection histories and failure modes of the stub columns are reported. The test results were employed in a parallel numerical simulation programme for the validation of the finite element (FE) model, by means of which an extensive parametric study was undertaken to extend the available results over a wide range of cross-section slendernesses, inner tube strengths and concrete grades. The experimentally and numerically derived data were then employed to assess the applicability of the existing European, Australian and North American design provisions for composite carbon steel members to the design of the studied CFDST cross-sections. Overall, the existing design rules are shown to provide generally safe-sided (less so for the higher concrete grades) but rather scattered capacity predictions. Use of an effective concrete strength is recommended for the higher concrete grades and shown to improve the consistency of the design capacity predictions.

ABSTRACT: The concept of local buckling of compressed isotropic cylindrical shells is developed in this paper. Buckling of axially compressed cylindrical shells under different types of local perturbations has been studied in many theoretical and experimental researches. Different methodologies, based on these studies, were suggested for design buckling load estimation. However, in most calculations and experiments only two classical boundary conditions were considered: fixed displacement of the shell edges in the axial direction or fixed and uniformly distributed compressive load. Both of them are hard or even impossible to realize in practical applications. In the present paper we studied the shell behaviour with 6 different types of boundary conditions, which included the above mentioned two types. We considered shell loading through rigid plates with different types of possible displacements (degrees of freedom) and through stiffening ribs at the edges of the shell. Two theoretical methods were applied: numerical (finite element method) and analytical (Pogorelov's geometrical method). Lateral force was applied as a perturbation and stability of the shell under load combination was studied. The results of calculations were compared with obtained experimental data for validation of numerical solutions. Then metastability and post-buckling behaviour of the structure was studied using theoretical and experimental methods. In particular the interval of existence and stability of post-buckling equilibrium states of the shells with one or several buckles was studied systematically. The post-buckling equilibrium paths and corresponding energy barriers for all mentioned types of boundary conditions were analyzed. Parametric analysis of boundary value problem allowed to establish the main (Batdorf) structure parameter. Formula for design buckling load was suggested and discussed.
ABSTRACT: The differences in the mechanical performance of prismatic and non-prismatic beams with concrete flanges and corrugated steel webs (CSWs) are numerically investigated in this paper with respect to their behaviour in bending, shear and shear buckling. With regard to the bending behaviour, it is found that the quasi-plane assumption is still valid for the non-prismatic beams with CSWs, similar to the prismatic beams with CSWs, at their elastic stage and their bending stiffness are mainly provided by the concrete flanges. This is attributed to the accordion effect of such webs. In terms of the shear behaviour, it is found that the inclined bottom flange shares a significant portion of the shear force in the non-prismatic beam with CSW, while the effective shear force carried by the CSW is greatly reduced; this phenomenon is called the Resal effect which is the most important reason leading to the shear performance difference between the prismatic and non-prismatic beams with CSWs. Thus, the traditional calculation assumption that the CSWs bear all the vertical shear force in the prismatic beams with CSWs is no longer applicable in calculating the shear stress in the non-prismatic cases. Additionally, it is noticed from two numerical cases, simulating the prismatic and non-prismatic beams with CSWs under end loading, that the average shear stress in the CSW of the non-prismatic beam decreases gradually from the free-end to the fixed-end with the increase of the hogging bending moment, while the shear stress in the CSW remains nearly constant in the prismatic beam. The numerical results, as well, show that the root cross-section, although it bears the maximum bending moment and shear force, is not the critical shear section of the CSW of the non-prismatic beam. Finally, considering the shear buckling behaviour, it is found that the shear buckling stress of the non-prismatic with CSW is much greater than that of an equal-weight prismatic beam with CSW through eigenvalue buckling analyses.

ABSTRACT: The steel-concrete composite structure using the high-strength steel (HSS) is featured with high strength, lightweight and economic benefits. In this study, a finite element model was established to simulate the compressive behavior of concrete-filled double-skin steel tubular (CFDST) stub column using high-strength steel. The material nonlinearity, the confinement effect and the contact behavior were considered. A total of four large-scale CFDST stub columns using HSS in the outer tube were tested under axial compression. The model was validated using both current and previous test results. The verified numerical model was then used to analyze the influences of various parameters, such as the yield stress of steel, the hollow ratio and the confinement factor. Furthermore, the feasibility of current design equations for CFDST columns using HSS was assessed. It was found that the HSS tube worked well with the sandwiched concrete, and the current methods could provide reasonable yet conservative predictions on the compressive strength of CFDST stub columns using HSS.

ABSTRACT: In this work, a finite element based optimization methodology is developed to obtain the optimal designs of thin-walled open cross-section columns for maximum buckling load. As a constraint for the optimization study, the total material volume of the column is kept constant. At first, an analytical formulation based on Bleich's (1952) approach, which considers the combined effect of both torsional and flexural buckling, is used to validate the finite element buckling load computation in ANSYS. Subsequently, these finite element buckling results are coupled with a Genetic Algorithm (GA) based optimization routine in MATLAB to obtain the optimal design of the cross-section of the columns. Optimal results are compared with a base model of the column having a cruciform cross-section. The optimization of the cross-sections results in remarkable enhancement, up to as high as 236%, in the maximum buckling load capacity compared to the base model.

ABSTRACT: The crash box is a structural component which is widely used in transport vehicles. It is designed to collapse and absorb kinetic energy in a low-speed collision. In this paper, we present a family of new origami crash boxes with rectangular, polygonal cross sections, and tapered shapes, through pre-folding the surface of thin-walled tubes according to a set of developable origami patterns. We have demonstrated through quasi-static impact experiments and numerical simulation that these origami crash boxes collapse into a diamond-shaped mode with a doubled number of traveling plastic hinge lines. The proposed optimal design leads to a maximum increase of 107.1% in terms of the energy absorption per unit mass and a maximum reduction of 68.3% of the initial peak force when compared with the conventional crash box. The substantial gain in overall energy absorption and the decrease in peak reaction force makes the proposed origami patterns attractive for energy absorption applications.

ABSTRACT: In this paper, an extensive numerical study is performed with the aim to investigate the elastic buckling behavior of simply supported cylindrically curved steel panels subjected to a pure shear load. The main objective is to understand the influence of geometrical parameters, such as curvature and aspect ratio, but also of the edge in-plane constraints. Finally, a new formula is proposed, which allows simple and accurate estimation of the critical shear stress of unstiffened curved panels with three different types of edge constraints, for various curvatures ($1 < Z \leq 100$) and various aspect ratios (up to 5).

ABSTRACT: The application of aluminium alloy members in building construction has considerably increased in recent years due to their appealing advantages such as corrosion resistance and high strength-to-weight ratio. However, the elastic modulus of aluminium is only one-third of that of steel, making aluminium members being susceptible to various buckling modes including web crippling. To date, only a limited amount of research study has been conducted to investigate the web crippling failure phenomenon in aluminium structural members, and no research has been carried out on the web crippling behaviour of roll-formed aluminium lipped channel sections. Hence, an experimental study was conducted to assess the web crippling behaviour and capacities of unfastened aluminium lipped channel sections under two flange load cases (End-Two-Flange (ETF) and Interior-Two-Flange (ITF)). Forty tests were performed with different bearing lengths, web heights and thicknesses. The results obtained from this study were then compared with the nominal web crippling strengths predicted using the design rules provided by the Australian, European and American Standards. The comparison showed that the current design equations are potentially unsafe and unreliable to estimate the capacity for aluminium lipped channel sections under both ETF and ITF load cases. Hence, suitable modifications were proposed to the available design equations based on the experimental results to accurately predict the web crippling capacities of aluminium lipped channel sections. Generally, it is shown that the web crippling results acquired from the modified equations agreed well with the test results.

ABSTRACT: Residual stresses and initial geometric imperfections have important effect on the buckling resistance of slender plated steel structures. Despite their large importance, the actual knowledge on residual stresses and exact geometric imperfections are limited, especially for corrugated web girders. In the accompanying paper [1] (Part 1) a finite element model of corrugated web girders is introduced and verified, which is able to virtually simulate the manufacturing process (cold-forming; cutting, welding) of corrugated web girders. The presented numerical model is able to determine the actual imperfection shape and residual stresses which are specific for the actual girder geometry and manufacturing method. The numerical model is
further developed for simulating geometrically and materially nonlinear analysis with imperfections (GMNIA) on the virtually manufactured specimens to determine the shear buckling resistance. The effect of manufacturing imperfections on the shear buckling resistance is evaluated for several different corrugation geometries and the obtained tendencies are evaluated and discussed in the current paper.

ABSTRACT: The treatment of cold-formed steel sections in design codes is very largely restricted to individual members under ideal conditions. More efficient design is possible if the complexities of the structural response caused by the thin plating and complex shapes, together with the actual conditions of load introduction and restraint arising from practical situations can be recognised. Traditionally this has only been possible by resorting to full-scale testing. This is, of course, time consuming and expensive; moreover, the impossibility of covering all variations of all the important problem parameters means that developing a comprehensive understanding of all aspects of the physical behaviour is unlikely. Numerical analysis offers the promise of an alternative approach. However, for this to be reliable there must be confidence that it accurately models the physical situation. For the past decade a programme of research has been underway aimed at the provision of a more complete understanding of the structural behaviour of cold-formed steel sections when employed in particular practical situations. Three such cases are addressed herein: purlins as used in the roofs of industrial buildings, beams used to support floors and columns forming part of a stud wall framing system. In each case the process has been to firstly identify all the important structural components including fastening arrangements, then to develop numerical models using ABAQUS that represent each of these physical features to a sufficient degree of accuracy, then to validate the models by comparison with all available test data, then to conduct parametric studies covering the full range of variables found in practice and, finally, to use the pool of results and the improved insights into behaviour as the basis for improved design approaches that, by more accurately capturing the key physical features, provide better predictions of performance. An important feature of this has been to ensure that the resulting design procedures were the simplest possible consistent with reliable predictions.

ABSTRACT: This paper presents the formulation of a three-dimensional beam finite element (FE) that accounts for cross-section warping and dynamic inertia effects. The model is the extension of an existing mixed formulation, originally developed for the static analysis of thin-walled beams, to the case of dynamic loading conditions.

Four independent fields are considered to derive the element governing equations, i.e. material rigid displacements, strains and stresses and an additional displacement field, describing the out-of-plane warping displacement of the beam cross-sections. The latter is independently interpolated in the element volume by including additional degrees of freedom (DOF) to the nodal translations and rotations classically considered in beam formulations.

To obtain a consistent form of the element mass matrix, the cross-section displacement shape functions are computed, relating the generalized cross-section displacement fields to the element nodal variables. In mixed FE formulations, these are not assigned a priori, as in displacement-based approaches, but are derived on the basis of material stiffness and element geometry, together with compatibility conditions. Thus, the Unit Load method is applied to deduce the expressions of the shape functions consistent with the force-based approach, assuming the simply-supported beam as reference element configuration.

As opposed to the original FE model, the additional warping DOFs are not condensed-out with the definition of the element quantities but are treated as additional global unknowns. This permits a correct description of the inertia effects and ensures continuity of the warping displacement fields between adjacent FEs.

Correlation studies are presented to validate the proposed model and investigate the effects of cross-section warping on the dynamic behavior of thin-walled structures. For selected specimens, the studies compare solutions obtained adopting the proposed beam element with those resulting from shell or brick FE models.
Modal decompositions and time-history analyses are conducted, assuming both linear elastic and nonlinear constitutive behavior for the latter.

ABSTRACT: A novel one dimensional beam model for analysis of prismatic thin-walled beams with deformable cross sections is introduced and a novel cross section mode determination procedure, which leads to the three dimensional beam displacement modes, is derived. The first order beam model for linear analysis includes: shear deformations related to both Timoshenko and Mindlin-Reissner type shear deformations, the warping effects of torsion, cross section distortion with related warping effects, as well as the Poisson effect with transverse displacements due to normal stress. The generality of the model allows it to handle open, closed and multi-cell cross sections with branched walls. The cross section analysis procedure leads to two types of beam displacement modes referred to as distortional beam modes and fundamental beam modes, with exponential and polynomial variations along the beam axis, respectively. It turns out that each of the beam deformation modes consists of a sum of one to four cross section displacement fields each with an individual axial variation. The displacement modes can facilitate the formulation of an advanced thin-walled beam element. The beam displacement modes will be illustrated for an open and a closed cross section.

ABSTRACT: This paper provides a review of recent developments in research and design practice surrounding the structural use of stainless steel, with an emphasis on structural stability. The nonlinear stress-strain characteristics of stainless steel, which are discussed first, give rise to a structural response that differs somewhat from that of structural carbon steel. Depending on the type and proportions of the structural element or system, the nonlinear material response can lead to either a reduced or enhanced capacity relative to an equivalent component featuring an elastic, perfectly plastic material response. In general, in strength governed scenarios, such as the in-plane bending of stocky beams, the substantial strain hardening of stainless steel gives rise to capacity benefits, while in stability governed scenarios, the early onset of stiffness degradation results in reduced capacity. This behaviour is observed at all levels of structural response including at cross-sectional level, member level and frame level, as described in the paper. Current and emerging design approaches that capture this response are also reviewed and evaluated. Lastly, with a view to the future, the application of advanced analysis to the design of stainless steel structures and the use of 3D printing for the construction of stainless steel structures are explored.

ABSTRACT: The un-stiffened fiber reinforced polymer (FRP) beams under three-point bending often fail at compression web-flange junction due to low inter-laminar shear and transverse compressive strengths of web. Therefore, the objective of the present work is to study the effect of different stiffening elements on the flexural response of FRP I-beams. Various stiffening elements such as glass fiber reinforced polymer (GFRP) cover plates, cover angles, and bearing stiffeners are connected to the beam separately to examine their effect on the strength, stiffness and failure modes. This study also includes the strengthening of web-flange junction of FRP I-beams using carbon fiber layers with adhesive. It is observed that replacing the chopped strand mats with 45° and 90° unidirectional rovings increases the crushing strength of the beam. Strengthening of web-flange junction using carbon fiber layers or stiffening with short length bearing stiffeners under loading is observed to be most effective in preventing the failure of web-flange junction of FRP I-beams. Beams stiffened with short length bearing stiffeners have higher failure load than other stiffened beams. Strengthening of web-flange junction using wet carbon fiber layers is noted to be more effective than stiffening with GFRP cover angles. Since the stress concentration produced due to the sudden change in the cross-section of beams strengthened with carbon fiber reinforced polymer (CFRP) laminated cover angle is less than that for beams stiffened with GFRP cover angles.

ABSTRACT: Unstiffened I-beams are prone to local and premature failure. Stiffened beams having improper stiffening technique or size of stiffening element may have lesser failure load than that of unstiffened beams. In this paper, flexural characteristics of stiffened and unstiffened FRP I-beams is determined analytically and numerically; and verified with experimental investigation. There are no code provisions for designing of FRP beams with stiffening elements. Hence, equation to calculate the deflection of beams with different stiffening elements is derived using Castigliano’s theorem. In order to get the better understanding of failure of FRP beams, various formulae for beams without stiffening elements available in design manuals are incorporated in the analytical model for prediction of failure load and mode. Further, a failure criterion is recommended for prediction of failure load of beams with and without stiffening elements. The results obtained from analytical and finite element models give the good comparison of results with experimental investigation. Further, a parametric study is performed on beams having different flange width-to-thickness ratios (5–15), depth-to-thickness ratios (21–40), and length-to-depth ratios (3–11) with different sizes of stiffening elements. It is observed that failure load of beams increases up to certain length of bearing plate, later it becomes constant. Under flexural loading, bearing stiffeners of a beam is found to fail, if the length of bearing plate is less than the flange width of T-shaped bearing stiffener. Similarly, if the length of cover angle or carbon fiber layer provided is less than the length of bearing plate, then the failure load is equivalent to the beam with having bearing plate only. Carbon fiber angles are less effective than beam with cover angle for effective depth-to-thickness ratio more than 21.

ABSTRACT: This paper presents a detailed treatment of the formulation for buckling and free vibration analysis of Bi-Directional Functionally Graded (BDFG) Thin-Walled non-prismatic beams of generic open/closed cross section. The theory developed is limited to small strains, moderate deflections and small rotations. It is based on the assumption that the shear strain on the mid-surface contour of the cross section of the member is neglected. Using the membrane theory of shells rigorous expressions for strains are obtained by which the effect of nonlinear tapering is considered. The material properties are assumed to be graded both in the longitudinal and depth-wise directions of the plate segment of the thin-walled beams. The governing equations are developed defining the displacements with reference to any arbitrary point (say geometric centre) and get away with the usual shear centre and centroid. For computer solutions for classical buckling and vibration analyses, the Finite Element Method is used. Simpson’s rule of numerical integration is adopted for the computation of axial, coupled and bending rigidities as well as inertial properties of the plate segment and the Gaussian Quadrature of numerical integration is used for the computation of flexural stiffness, geometric stiffness and mass matrices of an element over the length of the beam. Critical buckling loads and the natural frequencies and their corresponding buckled and mode shapes for various examples are obtained by solving as an eigen-value problem and compared with the published results in the companion paper.

ABSTRACT: In the current study, deflections, buckling loads, natural frequencies and the corresponding mode shapes and forms for BDFG thin-walled tapered beams of generic open/closed/open-closed sections are examined using the finite element method. A tapered thin-walled beam finite element with the seven degrees of freedom at each node is investigated. A rigorous expression for strains based on the membrane theory of shells is considered. The flexural stiffness matrix, geometric stiffness matrix and the consistent mass matrices are developed in a companion paper. Using the present theory, one is able to investigate various torsional, flexural static and dynamic systems. Examples are presented and comparisons are made with the existing available literature. With the modifications of axial, coupled and bending rigidities one will be able to investigate composite beams with fibre reinforced composite laminates.

ABSTRACT: This paper concerns the underpinning system reliability calibrations that will enable the implementation of the next generation of system-based design-by-analysis method of steel rack frames, i.e., a design approach where analysis and capacity checks are carried out in a single step by using fully nonlinear analysis. The paper details the design framework of the new approach, referred to as the Direct Design Method (DDM), and derives system strength statistics for five typical configurations of rack frames using Monte-Carlo simulations, taking into account the randomness of geometric and material properties. The nominal models of rack frames are developed in accordance with the Australian Standard AS4084. The mean-to-nominal ratios (bias) and coefficient of variation of the system strengths are obtained, and will be used in the companion paper to derive the system resistance factors consistent with a given structural reliability.

ABSTRACT: This is the second of two papers introducing the underpinning structural analyses and reliability studies that implement the system-based design-by-analysis method of steel rack frames, referred to as the Direct Design Method (DDM). The present paper presents the reliability analyses and derivation of system reliability index (β) versus system resistance factors (ϕ) curves. Results are presented for nominal system strengths as per Australian Standard AS4084 for several nominal models, including models that exclude sectional imperfections, and models without member and sectional imperfections. The effect of model uncertainty is also assessed. A detailed example of the DDM applied to the design of a rack frame is presented and the benefits of the DDM are demonstrated when compared to the traditional design approach which is based on elastic analysis.

ABSTRACT: Thanks to the larger and more continuous confining stress provided by hollow steel tube, ultra-high-strength concrete-filled-steel-tube (UHSCFST) columns are advocated rather than conventional transverse steel confined ultra-high-strength concrete. However, during elastic stage, de-bonding occurs as the Poisson’s ratio of steel is larger than that of concrete, whereas in post-elastic stage, confining stress, strength and ductility of concrete decrease since the steel tube would buckle. Thus, the composite action cannot be fully developed. To overcome these problems, external confinement in the form of tie bars, steel rings and steel spirals are proposed in this paper to increase the confinement effect of UHSCFST columns. A series of uni-axial compression test has been conducted to study the behaviour of externally confined UHSCFST columns. Results showed that the proposed confining schemes can effectively improve the strength, elastic stiffness and ductility of UHSCFST columns. Moreover, rings and spirals are more effective than tie bars. Lastly, a modified theoretical model based on that developed previously by the authors was used to predict the ultimate load and axial load-strain behaviour of the tested columns, in which excellent agreement between the theoretical and experimental results has been obtained.

ABSTRACT: Thin-walled structure is widely used in automobile, aviation and other industrial fields due to its lightweight, high energy absorption efficiency and low cost. Four thin-walled hybrid multi-cell structures with circular and square sections are proposed in this paper. The energy absorption characteristics and crushing deformation of the hybrid structures are investigated by experimental testing and numerical analysis. Meanwhile, the theoretical models of mean crushing force and specific energy absorption of the hybrid structures are developed by simplified super folding element (SSFE) theory. It is found from the sensitivity analysis of parameters that the dimension of the external tube (D) and the wall thickness (T) of the structure have significant effects on energy absorption. Furthermore, the multi-objective optimization including multiple
surrogate models is performed to obtain optimal crashworthiness of the hybrid multi-cell structures. The results show that multiple surrogate models are more favorable and accurate for the crashworthiness design, and the hybrid multi-cell structure with the outer circle and inner square section (CS.) has the best crashworthiness performance. Finally, the multi-objective optimization solutions are analyzed and chosen by the normal boundary intersection (NBI) method to carry out the crashworthiness comparison with the typical multi-cell structures of the same mass, and the hybrid structure (CS.) outperforms multi-cell tubes with the single circular or square section.

ABSTRACT: An FRP (fiber-reinforced polymer) -confined concrete filled steel tube is formed by the combination of FRP material and a concrete filled steel tube, and it combines the advantages of FRP-confined concrete and a concrete filled steel tube (CFT); however, there is still no effective model to generally describe the complete stress-strain curve of a concrete filled FRP-confined steel tube. The stress-strain response of a concrete filled FRP-confined steel tube features the dual characteristics of both FRP confined concrete and steel confined concrete. In this paper, ninety-six test results of FRP confined circular CFT columns under axial compression were collected from different researchers. The steel tube confinement index is taken as an additional key influencing parameter on the strength and deformation, and calculation methods for the ultimate strain, ultimate stress, peak strain and peak stress of a concrete filled FRP-confined steel tube are established by taking into account the steel tube confinement index. Moreover, the stress-strain model was developed to describe the complete stress-strain curve consisting of the four stages of a concrete filled FRP-confined steel tube. The proposed model reflects the characteristics of the stress-strain behavior of a concrete filled FRP-confined steel tube with good accuracy and simplicity.

ABSTRACT: This paper is devoted to solving the stacking sequence optimization problem of symmetrical laminated composite cylindrical shells subjected to hydrostatic pressure. First, a conventional genetic algorithm (GA) coupled with a finite element analysis optimization method is developed to search for the best laminations with the maximum buckling pressure. These optimal laminations share similar extensional stiffness coefficient ratios \( A_{11}/A_{22} \) and bending stiffness coefficient ratios \( D_{11}/D_{22} \) because the two ratios of the optimal lamination fluctuate slightly around a specific value. Based on this phenomenon, a stiffness coefficient-based method (SCBM) is then proposed. The method is integrated with the GA and the stiffness coefficient calculation to identify the lamination whose stiffness coefficient ratios \( (A_{11}/A_{22} \text{ and } D_{11}/D_{22}) \) are closest to those obtained previously. The effectiveness of the SCBM is validated by comparison with the optimal results. The proposed method is then extended to more complex symmetrical laminations. Finite element analysis is also coupled with the GA as a control group. Comparisons reveal that the two methods lead to similar characteristic laminate patterns and maximum buckling pressures, which suggests that the SCBM works well for complex laminations. Moreover, the SCBM is found to be significantly more efficient because it only needs to calculate the stiffness coefficients rather than analyse the entire structure during the optimization.

ABSTRACT: In this paper, an extensive numerical study is performed with the aim to investigate the post-buckling behavior of simply supported cylindrically curved steel panels subjected to a pure shear load. The main objective is to understand the influence of geometrical parameters, such as curvature and aspect ratio, but also it is aimed to examine how the level of the constraint of the edges affects the ultimate shear resistance. Finally, a new set of formulas are numerically derived, which allow estimation of the ultimate shear reduction factor of unstiffened curved panels with three different types of edge constraints, for various curvatures (up to 50) and various aspect ratios (up to 5). Moreover, the formulas use a similar base form as the one available in EN 1993-1-5 for the prediction of the ultimate shear load of a flat panel.
ABSTRACT: In this paper, we evaluate various multi-cell design concepts to optimize the crash performances of thin-walled aluminum tubes. The crash performances of the tubes are evaluated by means of two metrics: the crush force efficiency (CFE) and the specific energy absorption (SEA). The CFE and SEA of the tubes are predicted through the use of the finite element analysis software LS-DYNA. Experiments are also conducted to validate the finite element models. Thirty different multi-cell design concepts are evaluated in terms of CFE and SEA, and the best design concept is selected for further evaluation. Next, we perform surrogate-based optimization of the selected design concept, upon which we find that optimum design for maximum CFE which utilizes smaller wall thickness values (except the wall thickness of the inner tube) and larger tube diameters than those of the corresponding ones for the optimum design for maximum SEA. Additionally, the optimized designs exhibit remarkable CFE and SEA performances.

ABSTRACT: Thin-walled cylindrical steel silos are one of the key structures for storage of materials in many industries and agricultural sectors. They are susceptible to instability under wind pressure when they are empty or partially filled. This paper investigates numerically the wind buckling behavior of three sample steel silos with stepped walls composed of isotropic rolled shells. Wind load vertical and circumferential distributions were adopted from Eurocodes. Two proposed circumferential pressure distributions for an isolated silo and a silo in a group with a closed roof were taken into consideration. Moreover, the effect of additional inward pressure, proposed by Eurocode, on buckling capacity of vented silos with a small opening was evaluated. Accordingly, comprehensive 3D finite element models were used and detailed linear and non-linear buckling analyses were conducted. The wind buckling capacity of sample structures considering multiple amplitudes of initial imperfections was also assessed. The results obtained suggest a considerable decrease in the buckling resistance of imperfect silos. Finally, Eurocode provisions for the wind buckling stress design of un stiffened cylinders with step-wise variable wall thickness were examined and the relevant conclusions have been made.

ABSTRACT: A highly efficient and accurate semi-analytical domain decomposition method for elastodynamic problems of functionally graded elliptic shells and panels with elastic constraints on the basis of the first-order shear deformation theory is presented. Firstly, according to the first-order shear deformation theory, the dynamic energy functional of elastic shell structure is established. Then, the multi-segment partitioning technique is used to segment the shell along the circumference and axis direction. Thirdly, the modified variational principle and least-squares weighted residual method are adopted to ensure the inherent continuity between segments. On this basis, the virtual springs are evenly arranged on each boundary to simulate the boundary forces, and then the desired boundary conditions can be simulated. The displacements of each shell domain are expanded as double Jacobi orthogonal polynomials in the circumferential and axial variable. Lastly, the piecewise matrices for a segment are assembled directly in a similar way to that of the finite element method, and the elastodynamic problems of functionally graded elliptic shells and panels are obtained by the variational operation with respect to generalized coordinate vectors. The numerical comparison shows high computational efficiency and accuracy of the present method. All the calculation results in this paper can be used as benchmark data for future scholars to study this structure.

ABSTRACT: The approach to solving two-dimensional nonlinear (linear) boundary-value problems for shallow shells using the complete systems and quasilinearization Newton-Kantorovich-Raphson methods is developed. With the complete systems method in linear case, the original two-dimensional boundary-value problem is reduced to this system of two interconnected one-dimensional problems, which is solved iteratively using the
Thin shells subjected to various boundary conditions. The vibration equation is obtained by using the Lagrange equation method. In constraint to obtain the potential energy of linear vibration analysis of symmetrically 3-layer composite thin circular cylindrical shells with arbitrary boundary conditions, the edges of the shell, which can be universally applicable to all geometrical parameters, material properties, imperfection, the elastic foundations, eccentrically oblique stiffeners, mechanical loads and temperature on the nonlinear dynamic response and nonlinear vibration of plates. The numerical results in this paper are compared with the results reported in other reports.

ABSTRACT: This paper presents a semi-analytical approach to investigate the nonlinear dynamic response and vibration of eccentrically oblique stiffened functionally graded plate resting on elastic foundation. The Lekhnitskii's smeared stiffener technique is improved by using a transformation technique for oblique stiffeners. Governing equations are solved by classical shell theory, Galerkin method, stress function with temperature-dependent material effects. The results show the influences of geometrical parameters, material properties, imperfection, the elastic foundations, eccentrically oblique stiffeners, mechanical loads and temperature on the nonlinear dynamic response and nonlinear vibration of plates. The numerical results indicate the influence of boundary conditions, geometric parameters, symmetrical lamination schemes and damping coefficients on the nonlinear amplitude-frequency characteristics of symmetrically 3-layer composite thin circular cylindrical shells are investigated. The numerical results indicate that the present method is powerful to calculate the nonlinear vibration response characteristics of symmetrically 3-layer composite circular cylindrical thin shells subjected to various boundary conditions.

ABSTRACT: Cruciforms are frequently used as energy absorption components in engineering structures. The kirigami cruciforms (KCs) are designed by kirigami approach to simplify the manufacture process and reduce the initial peak force. However, the mean crushing force of KC is less than half of that of conventional cruciform (CC), which is negative for energy absorption purpose. The weak interaction between two component plates (plates A and B) in KC (no material connection) is a crucial factor for the decrease of mean crushing force. Therefore, laser welding technology is employed to enhance the connection between plates A and B by applying welding lines on the intersection line between components. Detailed analyses concerning the welding lines and boundary constraints are conducted to investigate the effect of connection between plates A and B. The results show that the mean crushing force of KC is close to that of CC if these conditions are met: the location of welding line is at the center of intersection line, and the length of welding line is no less than 30% and 43% of the length of cruciforms without and with symmetric boundary constraints on outside flanges, respectively. The conclusions indicate that the energy absorption capacity of thin-walled structure can be tuned by adjusting the connection strength between components in an energy absorption system.

ABSTRACT: Considering the large-deformation hypothesis, the modeling and nonlinear vibration characteristics of symmetrically 3-layer composite thin circular cylindrical shells with arbitrary boundary conditions are analyzed by applying four sets of artificial springs. Firstly, by employing a set of orthogonal polynomials and trigonometric functions, the energy equations of the shells are derived with Donnell's nonlinear thin-shell theory. Then, the arbitrary boundary conditions are simulated by imposing the equivalent elastic constraint to obtain the potential energy of the edges of the shell, which can be universally applicable to all classical boundary conditions. The vibration equation is obtained by using the Lagrange equation method. In order to obtain correct numerical results, several comparisons of linear and nonlinear results are carried out to validate the approach method in the present study; meanwhile, the calculation convergence is checked. At last, the influence of boundary conditions, geometric parameters, symmetrical lamination schemes and damping coefficients on the nonlinear amplitude-frequency characteristics of symmetrically 3-layer composite thin circular cylindrical shells are investigated. The numerical results indicate that the present method is powerful to calculate the nonlinear vibration response characteristics of symmetrically 3-layer composite circular cylindrical thin shells subjected to various boundary conditions.

ABSTRACT: In this study, the traditional Temcor joint (TR-Temcor) is modified using a central hollow hexagonal prism and some front bolts. The Finite Element Analysis (FEA) model is established and verified by experiments. Then, a parametric analysis is carried out for the improved Temcor joint (IM-Temcor). To obtain the optimal parameters for the modified joint, the key factors, namely: number and location of the front bolts, bolt-hole deviation, pretension force in bolts, thickness of front plate and heat-affected zone caused by the welding work, are considered in the FEA models. The modified joint, with the optimized factors, is analyzed for different static load conditions, considering axial pressure, axial tension, pure bending, bending with axial force, and eccentric axial forces. The overall mechanical behavior of the joint, including the $M$-$Φ$ curves, initial stiffness, ultimate strength and deformation capacity, as well as the failure modes are identified. The results from the improved joint are compared with corresponding values from of the traditional Temcor joints. The results show that the central hollow hexagonal prism and front bolts significantly improves the stiffness and ultimate strength of the joint, especially when the joint is subjected to pure bending, bending with shear force, axial force, bending with certain axial force and eccentric force.

ABSTRACT: The semi-analytical solution for nonlinear stability analysis of imperfect doubly-curved laminated composite shallow shells with rotationally-restrained edges and under in-plane loading is presented. The nonlinear governing equations are established using the Galerkin method, and the arc-length and quadratic control method is implemented to capture the snapping phenomenon of the doubly-curved composite shells. The nonlinear load-displacement relationships of four special curvature radii of doubly-curved shell structures are obtained, and they are compared and validated with the numerical finite element solutions. A parametric study is conducted to evaluate the effects of the initial imperfection, edge rotationally-restrained spring stiffness, various load parameters, and curvature radius on the nonlinear stability behavior of doubly-curved shells. Finally, the computational efficiency and capability of the semi-analytical solution are demonstrated in comparison with the finite element analysis. The present semi-analytical solution can be effectively and efficiently used in simplified nonlinear stability analysis of complex doubly-curved composite shallow shells with periodic and restrained boundary conditions.

ABSTRACT: This paper focuses on the nonlinear dynamics near internal resonance of a truncated FGM conical shell. The FGM conical shell is subjected to the aerodynamic load and the in-plane excitation along the meridian direction. Material properties depend on the temperature and the constituent phases of the truncated FGM conical shell. The volume fractions are modified in the thickness direction based on a power-law function continuously and smoothly. The first-order piston theory is applied for the supersonic aerodynamic pressure. Based on the first-order shear deformation theory, von-Karman type nonlinear geometric assumptions, Hamilton principle and Galerkin method, the nonlinear equations of motion for the truncated FGM conical shell are derived. The averaged equations of the truncated FGM conical shell are obtained under the situation of 1:1 internal resonance and 1/2 subharmonic resonance by using the method of multiple scales. The frequency-response curves, the force-response curves, the bifurcation diagrams, the phase portraits, the time history diagrams, and the Poincare maps are obtained by using numerical calculations. The influences of the Mach number, the exponent of volume fraction and the in-plane excitation on the nonlinear resonant behaviors of the truncated FGM conical shell are investigated.
ABSTRACT: One of the most effective nondestructive methods to estimate the buckling load of imperfection sensitive thin-walled structures is vibration correlation technique (VCT). Although this technique can determine the buckling load for several types of structures without reaching the instability point, it is still under development for composite sandwich plates and shells. In this paper, experimental and numerical verification of VCT approach are presented for the estimation of the buckling load of the composite sandwich plates with iso-grid cores loaded in compression. In the experimental section, four specimens are designed and fabricated using a new silicone rubber mold, and hand lay-up technique. The modal test is performed on the first specimen by exciting the sandwich plates using the modal hammer method in the different applied loads. Then, the variation of the natural frequency with the applied compressive load is recorded up to actual experimental buckling load. Besides, numerical models, including nonlinear effects, are created in full details to calculate the variation of the natural frequencies with the applied load, and to be compared with the experimental results. Finally, the buckling test is carried out on all specimens to validate the experimental and numerical results of VCT approach. The results demonstrate that the maximum difference between the predicted buckling load using the VCT approach on the experimental and numerical results with an experimental buckling load is less than 5%. Also, VCT provides a reliable estimate of buckling load when the composite sandwich plates with iso-grid cores have been loaded up to at least 67% of the experimental buckling load.

ABSTRACT: In this paper modal decomposition of thin-walled structural members with rounded corners is discussed. Modal decomposition is a process which separates the characteristic behaviour types. If modal decomposition is applied in buckling analysis, pure uncoupled buckling modes can readily be analysed, such as pure global buckling, pure distortional buckling or pure local-plate buckling. Ability to calculate critical loads to a pure buckling mode is highly beneficial in the design of thin-walled structural members, for example in the design of cold-formed steel beams or columns. However, cold-formed steel profiles are always produced with rounded corners, and earlier studies showed that the now-used modal decomposition techniques of the constrained finite strip/element method sometimes fail to lead to reasonable results if the rounded corners are directly modelled in the analysis. In this paper a special version of the constrained finite strip method is presented and discussed. The proposed method introduces elastic corner elements, which makes it possible to perform the modal decomposition by the same process used for members with sharp corners, even if the rounded corners are directly modelled, still the results of pure buckling modes satisfy the engineering expectations. The theoretical background of the proposal is briefly summarized, then the elastic-corner approach is discussed by detailed analysis of sample examples as well as by an extended parametric study.

ABSTRACT: Thermal and mechanical buckling analysis of micro plate reinforced with functionally graded (FG) graphene nanoplatelets (GNPs) is studied in this paper based on modified strain gradient theory (MSGT). For description of kinematic relations, two higher order shear deformation theories including third order shear deformation theory and sinusoidal shear deformation theory are employed simultaneously. Size-dependency is accounted in governing equations of thermal buckling by application of modified strain gradient formulation including three micro length scale parameters. Distribution of graphene nanoplatelets along the thickness direction is assumed based on various known models including Parabolic, linear and uniform. Halpin-Tsai model and rule of mixture are used for calculation of the effective modulus of elasticity and Poisson's ratio, respectively. The outputs of this work are verified through comparison with existing numerical results based on various theories and methods. Thermal buckling loads are calculated based on analytical method in terms of significant parameters such as weight fraction of GNPs, various distribution of GNPs, three micro length scale parameters, some non-dimensional geometric parameters such as side length to thickness ratio and thickness to micro length scale ratio.

ABSTRACT: This paper introduces a novel hierarchical core structure to sandwich panel for bearing the blast loading, in which each vertex of a regular hexagonal cell was replaced with a smaller hexagonal unit. The finite element (FE) models of such hierarchical honeycomb sandwich panels were established and validated with the experiments under different impulse loads. The hierarchical honeycomb cores were compared with the regular honeycomb counterpart in terms of the peak deflection on the back facesheet, compression and specific energy absorption (SEA) of the core. The results showed that the maximum deflection at the back facesheet of the hierarchical honeycomb sandwich panels were smaller than the regular honeycomb counterpart for a higher level of blast load (specifically, the dimensionless impulse higher than 0.06). It was found that the structural hierarchical parameter gamma (i.e. the ratio of the newly-introduced smaller hexagonal edge length (L) to the regular hexagon edge length (L0)), had limited influence on the maximum deflection of back facesheet of the sandwich panel, but had a significant effect on the SEA of the cores.

ABSTRACT: Bistable structures, a class of highly geometrically nonlinear morphing structures, have two stable configurations that remain in their respective equilibrium positions without the continuous application of an external force. This paper aims to summarise, review, and assess the literature about the theoretical studies, driving methods, numerical simulations, experimental investigations, and fields of application of the structures. The theoretical models are separated into anisotropic and isotropic composites based on the properties of the material. The generalised methods to study the bistability of structures with various properties are presented. The driving methods used to trigger the snap of one equilibrium structure to the other include mechanical force, piezoelectric actuation, shape memory alloy actuation, thermal actuation, and magnetic actuation. Numerical simulations of the curing process during manufacture and of the morphing process, which includes the snap-through and snap-back of the bistable structure, are reviewed. Moreover, the experimental investigations of structures with unsymmetric and antisymmetric layups are also presented. Bistable composite laminates and their structures have been used in aerospace, bionics, energy harvesting, and other fields due to their unusual behaviour and morphing potential. This paper also highlights the remaining challenges and possible future work on bistable composite transition, from phenomenon to potential applications.

ABSTRACT: Extensive numerical results available in published articles reflect the importance of the effects of geometric parameters, material properties, end conditions, hygrothermal fields, etc. on the behavior of laminated composite and sandwich structures when exposed to environmental conditions. A critical review of available literature for the prediction of the behavior of laminated composites and sandwich structures under hygrothermal conditions is carried out and summarized under different categories namely: static, vibration, buckling, post-buckling and miscellaneous studies (transient, dynamic, impact studies). Each category is further discussed separately in details highlighting the important outcomes of the research. In addition to that, each category is again grouped on the basis of the type of theory used by different researchers in their work. The displacement fields, thermal fields and the method adopted in different papers are also summarized.

ABSTRACT: Thin-walled cold-formed (TWCF) steel members are widely used in aerospace, automobile and architecture industries. Among the various advantages, mainly associated with the relatively simple and very cheap techniques required for their production and shaping, it is important to mention the relevant high strength to weight ratio. Beside the benefits, it has to be pointed out that the TWCF member response is quite difficult to
be predicted because of the significant influence of local, distortional and overall buckling phenomena, owing to the frequent presence of open mono-symmetric cross-sections.

The present paper can be intended as a typical technical paper whose results are useful not only for research activities, but, especially, for the routine design. It summarises a study aimed at increasing the safety of two European approaches that should be potentially adoptable for designing TWCF steel members. The grade of reliability of these existing European procedures has been evaluated by predicting the performance of more than 240 TWCF members tested in laboratory, selected in the framework of 13 experimental studies, taken from the literature. Being the assessed load carrying capacity sometimes significantly greater than the characteristic-experimental one, suitable safety factors have been consequently calibrated and proposed for each cross-section type, to be directly adopted in routine design to match the requirements associated with the limit state philosophy. Finally, the strength of additional TWCF beam-column specimens has been predicted to assess the efficiency of the proposed coefficients for practical cases frequently encountered in routine design. A complete benchmark is proposed in Appendix A, where the application of the considered design procedures for one selected case is reported.

ABSTRACT: Steel I-girders with slender web are commonly used in the engineering practice. Previous research results proved that the current bending and shear interaction (M-V) check of the EN1993-1-5 does not always provide safe side resistance. The current research work focuses on the analysis of the M-V interaction behavior of longitudinally unstiffened and stiffened I-girders with slender web. Applicability interval of the current EN1993-1-5 based M-V interaction resistance model is determined and based on the executed numerical investigation a refined M-V interaction equation is proposed to ensure safe and economic design. The results of the numerical parametric study also proved that the flange contribution in the shear buckling resistance does not match the current design rules of the EN 1993-1-5. In a specific parameter range (girders with light flanges) the current design rule underestimates the flange contribution to the shear buckling resistance leading to conservative resistances. However, for I-girders with heavy flanges the current design method gives unsafe results. Therefore, the current paper presents an improved formula to the flange contribution ensuring better approximation of the computed resistances.

ABSTRACT: The paper presents an experimental investigation on cold-formed high strength steel tubular T-joints. The fabricated T-joints include brace members made up of square, rectangular and circular hollow sections, while chord members were made up of square and rectangular hollow sections. The nominal yield strengths of square and rectangular tubular members were 900 and 960 MPa, while the nominal yield strength of circular tubular members was 900 MPa. Two configurations of tubular joints were fabricated, first, where both brace and chord members were made up of square and rectangular hollow sections, and second, where circular hollow section braces were welded to square and rectangular hollow section chord members. The brace and chord members were joined together by automatic gas metal arc welding process. In total, 24 tubular T-joint tests were conducted where an axial compression was applied through the brace members of the T-joints, while the ends of the chord members were supported on rollers. The ratios of brace-to-chord width (β) ranged from 0.34 to 1, brace-to-chord thickness (δ) ranged from 0.52 to 1.27 and chord width-to-chord thickness (2δ) ranged from 20.63 to 38.55. The resistances and deformations of tubular T-joints were carefully examined. In order to evaluate the applicability of the existing design provisions for high strength steel tubular T-joints, test results were compared with the nominal strengths obtained from the Eurocode 3 (EC3) and CIDECT. It is shown that the existing design provisions are not capable of providing accurate and reliable predictions for the design of cold-formed high strength steel tubular T-joints made up of S900 and S960 steel grades.

ABSTRACT: Storage rack structures are pre-engineered light weight steel structures with standard details which can be quickly assembled because all building components arrive on site pre-fabricated in line with the agreed design. Since they are made using thin-walled perforated steel sections, mostly cold-formed, with mechanical joints, generally partial-strength, semi-rigid, and with a low structural redundancy, these structures are vulnerable to any action capable to induce a local damage of a member or connection. When heavily loaded, the local damage may spread progressively, generating an overall collapse or disproportional damages. Difficulties in predicting the structural behavior of storage pallet racks are amplified by the specific geometry of the structural components: members made by high slenderness thin-walled and open-section profiles (hence prone to global, local and distortional buckling problems), flexible beam-upright and baseplate connections with a non-linear behavior. Due to their peculiarities, additional modelling and design rules are required for these non-traditional steel structures and reference cannot be made to usual structural design recommendations and standards. In case of Selective Pallet Rack (SPR) structures, except for the earthquakes, collision of forklift trucks or other moving equipment with front upright is considered as one of the most frequent causes of local failure, with potential to develop into a progressive collapse. In the study, the robustness of SPR structures under accidental loading situations involving collision with forklift truck is assessed using both notional upright removal and explicit forklift impact approaches. Structural configurations are varied to consider different connection properties (upright base and beam-to-upright) and brace arrangements (spine bracing, top plan bracing). SPR structures are susceptible to global failure, especially if the spine bracing is in just a few spans and the rigidity of connections is low. The explicit modelling of the forklift impact provides the most accurate results, as the effects associated with the forklift impact are not properly captured when the response is evaluated using the dynamic analysis and notional upright removal approach. Non-linear static pushdown analysis can provide satisfactory results at the least computational effort, but the dynamic increase factors may require corrections.

ABSTRACT: In this research, the buckling behavior of thin walled composite shell with embedded shape memory alloy (SMA) wires is examined numerically. To model the SMA wire properties, constitutive equation of Brinson is used and a UMAT subroutine is developed to link with ABAQUS finite element (FE) model performed to simulate the buckling behavior of composite shells. To validate the FE modeling, some experimental specimens are fabricated by filament winding process and tested under axial compressive loading to analyze the buckling behavior of the structure. The results show that the numerical model has sufficient accuracy and the effect of tensile pre-strain and the number of embedded SMA wires on the buckling capacity of the cylindrical composite shell are investigated. As the results obtained, by embedding 4 SMA wires without pre-strain in composite shell, the critical buckling load increases about 35%. Also, by increasing the pre-strain and the number of SMA wires (more than 4), the stiffness of the structure and the magnitude of the critical buckling load are decreased.

ABSTRACT: Concrete-filled stainless steel tubular (CFSST) columns combine the advantages of composite action seen in concrete-filled steel tubular (CFST) columns with the durability benefits associated with stainless steel. An effective means of reducing the material usage in the outer stainless steel tube in CFSST columns is to embed an inner carbon steel profile. This enables the material costs to be reduced, while achieving similar load-bearing capacity and durability, as well as enhanced fire resistance. The behaviour of such steel reinforced composite columns, i.e. concrete-filled stainless steel tubular (CFSST) columns with outer square cross-sections and embedded carbon steel profiles, under ISO 834 standard fire conditions is investigated in this study by finite element (FE) analysis. Firstly, FE models are developed and validated against relevant published experimental data on CFSST and steel reinforced CFST columns under fire conditions. Based on the validated FE models, the
working mechanisms of the studied steel reinforced CFSST columns under fire conditions are investigated by analysis of the temperature field, failure modes, axial deformation versus time response and internal force distribution. The fire performance of the studied steel reinforced CFSST columns is also evaluated in comparison with CFST and CFSST columns with the same total cross-sectional area of steel or the equivalent cross-sectional load-bearing capacity at ambient temperature. Finally, with respect to fire resistance, the optimal ratio of the cross-sectional areas of the inner carbon steel profile to the outer stainless steel tube is investigated.

ABSTRACT: Concrete-filled steel tubular (CFST) truss is a type of composite structure with CFST chords and hollow tubular braces. CFST trusses have been increasingly used in large-scale structures such as towers, bridge girders, piers and arch ribs. The compression and flexural behaviour of CFST trusses are greatly improved compared to hollow tubular trusses due to the concrete infill in chords. With the complex configuration, nonlinear material interaction and sophisticated construction process, initial imperfections may largely affect the strength and stability of a CFST truss structure. Relevant studies in the past mostly focused on one single type of imperfection with assumed magnitude in CFST member whilst in reality a variety of combinations of steel and concrete imperfection exist. This paper develops a nonlinear analysis formwork with the reliability analysis of CFST truss with random imperfections based on on-site measurement data and Monte-Carlo (MC) simulations. Advanced nonlinear finite element analysis (FEA) that can account for the material interaction and confinement in CFST trusses is established and validated by reported test data. The flexural behaviour of CFST trusses with deterministic and probabilistic initial imperfections are evaluated and compared, based on which the reliabilities and related system resistance factors in regards to random initial imperfections are proposed.

ABSTRACT: In this study, a finite element model was established and validated to investigate the mechanical behaviour of the latticed-sleeved compression member with strip core. Failure mechanism of the latticed-sleeved compression member was studied based on the core moment distribution and the effects of three reinforcement methods to increase the ultimate bearing capacity were compared. A parametric study was performed to investigate the effects of essential factors on the mechanical behaviours of the latticed-sleeved compression members. A method was adopted to control global buckling of the latticed-sleeved compression members. Based on the latticed-sleeved compression member, a capacity-monitoring member was introduced to control buckling and monitor the bearing capacity of the key compression member. It is concluded that: the latticed-sleeved compression member has a greater resistance to buckling; mutual effects exist between the two failure modes, local buckling of the core segment and global buckling of the latticed-sleeved compression member; the gap between the core and sleeve, the sleeve stiffness and the core protrusion length above sleeve have effects on the mechanical behaviors of the latticed-sleeved compression members; the adopted method considering the mutual effects between the two failure modes can effectively control global buckling of the latticed-sleeved compression members; and the bearing capacity of latticed-sleeved compression member can be monitored through measuring the resultant axial force of the connecting bolts.

ABSTRACT: The behaviour of cold-formed lean duplex stainless steel columns at elevated temperatures was investigated. A numerical investigation on columns of square and rectangular hollow sections were performed at elevated temperatures ranged from 24 to 900 °C. A validated numerical model with material properties obtained from tensile coupon tests at elevated temperatures were used in the finite element analysis. A total of 180 numerical column strengths were compared with design column strengths predicted by existing design rules, which do not cover the lean duplex stainless steel material at elevated temperatures. Reliability analysis was carried out to assess the suitability of the existing design rules for lean duplex stainless steel columns at elevated temperatures. It is shown that the existing design rules are generally not suitable for predicting the column strengths, except for the American Specification and the modified direct strength method for stainless
steel. The modified direct strength method for stainless steel provides accurate and reliable predictions with relatively simple calculation procedure. Therefore, it is recommended that the modified direct strength method for stainless steel be used for design of cold-formed lean duplex stainless steel columns at elevated temperatures.

ABSTRACT: The aim of this work is to investigate the effects of kinematics approximation on post-buckling analysis of sandwich structures. To this end, a novel one-dimensional (1D) layer-wise model is proposed, where the core is approximated by Mac Laurin's polynomial functions, and the skins are modelled by Euler-Bernoulli beam theory. The resulting nonlinear equations are solved by the Asymptotic Numerical Method (ANM), in which the bifurcation indicator is introduced to precisely detect the bifurcation points and the corresponding instability patterns. By varying the polynomial order in the core, various kinematics models are generated automatically, and then evaluated in the post-buckling stage. According to the comparison results, we finally propose an optimized model that is valid in a wide range of geometric and material parameters.

ABSTRACT: This research aims to investigate the free vibration characteristics of a nanoplate sinking in an incompressible fluid, so that the plate is in touch with the fluid from its upper surface. The nonlocal continuum theory together with Gurtin-Murdoch elasticity theory are employed to examine the influence of size-dependency and surface energy effect, respectively. In order to model the fluid-plate interaction, the Navier-Stokes equation is utilized, and the motion equations are solved through implementing Galerkin weighted residual method. The results show that the impact of fluid on shifting the nanoplate natural frequencies to the lower values highly depends on the small-scale parameter. Furthermore, for certain value of the length-to-thickness ratio, while the effects of nonlocal and surface energy parameters are considered to be negligible, the natural frequencies of the submerged nanoplate significantly overestimate the values obtained in the presence of these parameters. This means that, in order to precisely predict the system natural frequencies, it is important to include the impact of size-dependency and surface energy in the mathematical formulation.

ABSTRACT: The wide application of aluminum alloys has been spread in the field of civil and building engineering due to their excellent performance and advantages. The companion paper (Part I) has described the eccentrically compressive loading tests and the verification of finite element (FE) models. In this paper, a parametric study about the 6082-T6 aluminum alloy columns of square and circular hollow sections (SHS-CHS) subjected to eccentric compression was performed using the verified FE models. The key parameters affecting the buckling behaviors and ultimate strength were investigated, including the regularized slenderness ratio, eccentricity, width-thickness ratio (for SHS columns) and diameter-thickness ratio (for CHS columns). The ultimate strength obtained from the previous loading tests and the finite element analysis (FEA) were compared with the design strength predicted by the current Chinese (GB 50429), European (Eurocode 9), American (AA-2010) design codes for aluminum alloy structures. In addition, the newer proposed design method – the direct strength method (DSM), were also investigated. It was found that these four design provisions were generally conservative for predicting the ultimate strength of the SHS and CHS columns for 6082-T6 aluminum alloy and DSM was shown to provide more accurate strength predictions than the current design codes. Finally, the optimal distribution types of the model error (ME) in the four design provisions were investigated and reliability analysis was conducted under different load ratios to evaluate the safety levels of the three current design codes and DSM. Revised Chines code was proposed to predict the ultimate strength of 6082-T6 aluminum alloy columns more precisely.

ABSTRACT: The vibrational behavior of multilayer functionally graded graphene platelets reinforced composite (FG-GPLRC) toroidal panels with elastically restrained against rotation edges is investigated. The first-order shear deformation theory (FSDT) of shells together with the finite element method (FEM) is employed to develop a general formulation and solution procedure. Nine-noded isoparametric shell elements with five degrees of freedom per node are used to discretize the spatial domain. After validating the approach, the influences of different distribution patterns of graphene platelets (GPLs) through the panel thickness, the geometrical parameters, and the elastic coefficients of the rotational springs are studied. It is shown that among the multilayer FG-GPLRC toroidal panels with different GPLs distribution patterns, the toroidal panels with X-type pattern have the highest frequency values whereas the minimum values belong to the shells with O-type and -type for the first and second frequency parameters, respectively. Also, the numerical results reveal that by increasing the GPLs volume fraction and the elastic coefficients of rotational springs, the frequency parameters increase, and these parameters have considerable effects on the frequency parameters. Also, the mode shapes of multilayer FG-GPLRC toroidal panels for different GPLs distribution patterns are depicted.

ABSTRACT: For the design of thin-walled spherical shells under external pressure empirical knockdown factors are applied. These knockdown factors are based on experimental results from the beginning of the 20th century and have been shown to be very conservative for modern shell structures. In order to determine less conservative and physically based knockdown factors for the design of spherical shells, different analytical and numerical design approaches have been developed. In this paper common as well as new shell design approaches are presented in detail and evaluated regarding the lower-bound buckling pressure. Among these design approaches are the reduced stiffness method, measured geometric imperfections and perturbation approaches. Important analysis and modeling details of each design approach are described, and test examples are given and validated. Advantages and disadvantages of each approach are listed, and design recommendations are given. Practical shell buckling design examples are demonstrated by means of a tori-spherical bulkhead and a deep-sea spherical pressure hull. In addition, a collection of about 700 experimental knockdown factors for spherical shells under external pressure is given in the Elsevier repository.

ABSTRACT: Aluminum alloys, which function as load-bearing components or decorative materials, have been commonly applied to architectural structures. In this study, a combination of experiments and finite element analyses was conducted to investigate the stability behaviors and ultimate strengths of the 6082-T6 aluminum alloy columns subjected to eccentric compression. Prior to the loading tests, tensile coupon tests and measurement of the initial geometric imperfections for the columns were performed. The buckling behaviors of 30 pin-ended specimens, including 11 extruded square hollow section (SHS) columns and 19 extruded circular hollow section (CHS) columns, were investigated and the observed failure modes of the tested columns included overall buckling, local buckling and the coupling modes. Meanwhile, the ultimate strengths, deflections and surface strains in whole process under eccentric compression were recorded. The finite element (FE) models of the tested columns were developed using the non-linear finite element analysis (FEA) software ABAQUS, and the geometric and material nonlinearities were considered in the FE models. The validation of the FE models was performed against the test results; it was observed that the proposed FE models are sufficiently accurate to predict the ultimate strengths and buckling behaviors of the tested columns.

ABSTRACT: This is the first research on the nonlinear vibration analysis of composite sandwich doubly curved shell with a flexible core integrated with a piezoelectric layer. By using the higher order shear deformable theory (HSDT) for the face sheets and the third-order polynomial theory for the flexible core, the strains and stresses are obtained. It is assumed a smart model including multiscale composite layers shell with a flexible core and magnetorheological layer (MR) that leading up by the nonlinearity of the in-plane and the vertical displacements of the core. Three-phase composite shells with polymer/Carbon nanotube/fiber (PCF) and polymer/Graphene platelet/fiber (PGF) and Shape Memory Alloy (SMA)/matrix either according to Halpin-Tsai model have been considered. The governing equations of multiscale shell have been derived by implementing Hamilton's principle and solved by multiple scalar method. For investigating the correctness and accuracy, this paper is validated by other previous researches. Finally, the effect of different parameters such as temperature rise, various distributions pattern, magnetic fields and curvature ratio are explored in detail.

ABSTRACT: The aim of the current work is to present a shear deformation theory which can model the free vibration of functionally graded nano-size beams made of two different types of materials (isotropic and anisotropic) resting on elastic foundation using a new shear strain shape function. The proposed model includes undetermined integral term and also contains both transverse shear and stretching effects. The size-dependent behavior of nano-size systems is captured via the nonlocal strain gradient theory. The governing equations of motion are obtained based on a virtual work of the Hamiltonian principle where an analytic technique based Navier series is established to solve the eigenvalue problem. From our knowledge, it is the first time that size-dependent dynamics of graded nanobeams made of anisotropic materials is investigated. The efficiency of the present model is verified by comparing the results of numerical examples with the different solutions found in the literature. It shows that the dynamic characteristics of the nanobeam are influenced by size effects, geometry, power-law index, exponential factor, and elastic foundation. Also, the possibility and accuracy of replacing a hexagonal model with isotropic one is investigated and discussed in detail.

ABSTRACT: Adoption of cylindrical shell structures for various load-resistance applications has enjoyed widespread acceptance in the field of civil, mechanical and aerospace engineering, mainly due to the exceptional structural efficiency of cylindrical shells to withstand significant longitudinal and circumferential in-plane loading without bending. However, where such in-plane loading conditions are compressive, cylindrical shells are likely to exhibit an unstable response characterized by localized out-of-plane deformation. Computerized numerical simulation is often required for accurate and efficient estimation of the strains and resultant stresses in cylindrical shells under loading, especially where the thickness of the shell is sufficient to evoke an inelastic buckling response in the structure. The buckling behavior of thin-walled cylindrical shells subjected to uniform axial compression has been studied in this paper using the finite element (FE) simulation method to assign respective material, geometric, loading and boundary properties to computer-generated cylindrical shell specimens. Extensive parametric analysis, consisting of approximately 720 FE runs, was then conducted based on a full-factorial empirical design, applying ample variations of the relevant parameters that influence the buckling response of axially-compressed cylindrical-shell structures. Nonlinear multiple regression techniques were then employed to derive the coefficients of nonlinear mathematical expressions, each developed as an arithmetic product of appropriate variable functions related to the respective functional sensitivities of the investigated parameters. Strain-hardening properties were incorporated into the mathematical expressions based on the shape constants of the Ndubuaku stress-strain model; which has proven to be remarkably useful for accurate parameterization of the stress-strain behavior over the full range of strains for a wide range of metallic materials, including materials with a well-defined yield plateau. Excellent predictions of FEA-derived values.
for the critical limit strain limit were obtained, and a simple statistical approach was presented to increase the conservativeness of the semi-empirical model as required.

ABSTRACT: Damage caused by corrosion is one of the main factors that diminish the performance of thin-walled structures such as pipelines. Using experimental and numerical methods, this study investigated the effects of corrosion depth and corrosion shape on the performance of corroded thin-walled steel pipes when subject to combined internal pressure and 4-point bending load. The effect of corrosion depth was studied using three API 5 L X52 grade pipe specimens with a nominal diameter of 8-inches (203 mm), and the effect of corrosion shape was investigated by testing five API 5 L X46 specimens with a nominal diameter of 6-inches (152mm), containing different corrosion shapes. It was found that increasing the corrosion depth drastically decreases the bending capacity of the corroded specimens. Also, it was observed that the specimens with circular and square corrosion shapes exhibited the same bending behaviour, and extending the corrosion along the circumferential direction of the pipe wall caused the most negative effect on the bending behaviour of the specimen.

ABSTRACT: This paper investigates the shear behaviour of Hybrid stainless steels (HSS) plate girders using the commercial FE software, Abaqus. Two types of stainless steel grades were adopted viz., Lean duplex stainless steel (LDSS) for web and Duplex stainless steel (DSS) for flanges. The FE results are presented in the form of shear capacity (V) and failure modes. Based on the study, it has been observed that web thickness (t) has higher positive influence on the shear capacity as compared to flange thickness (t). On the other hand, relative improvement in ductility could be seen when flange thickness is increased, in contrast to increase in web thickness (t). In general, three failure modes were observed in HSS plate girders viz., shear dominant failure mode, bending dominant failure mode and combined shear and bending dominant failure mode. Based on the present results, modified Eurocode and Direct strength method (DSM) design formulations have been proposed.

ABSTRACT: In this paper, the axisymmetric buckling of circular strain rate sensitive tubes subjected to axial impact is investigated theoretically and experimentally. The nonlinear governing equations are first derived in an incremental form. Then, the finite difference method is employed to solve the obtained equations implicitly for the case when a stationary tube is impacted by a striking mass. Experimental tests are performed by using a gas gun. The effect of linear and multi-linear approximation for strain hardening and strain rate on the shortening, buckling shape and axial force of steel tubes are investigated in which the strain rate is considered as a function of time. By applying the strain rate effect and using the multi-linear approximation for strain hardening, we showed there is a significant association between theoretical and experimental results of steel tubes. Also, using the nonlinear dynamic equations and newly developed inexact finite similitude theory it is revealed that the response characteristics of full-scale strain rate sensitive tubes can be predicted using small-scale strain rate insensitive tubes.

ABSTRACT: The present work discusses the development of a formulation for efficiently analyzing variable-stiffness plates operating in the post-buckling regime. The approach relies upon the combined use of a single-mode Koiter’s perturbation strategy along with a mixed variational formulation expressed in terms of Airy stress function and out-of-plane displacement, where the unknowns are approximated using global trial functions
A highly efficient numerical tool is achieved, which allows the initial post-buckling field to be analyzed with the ease of closed-form solutions, but a much wider field of employ in terms of elastic couplings, boundary and loading conditions. The quality of the predictions is illustrated by means of a comprehensive set of comparisons against results from the literature. Possible applications of the approach are shown, where the exploration of the design space offered by curvilinear fibers requires thousands of non-linear post-buckling analyses to be run.

ABSTRACT: A solution to the ‘modal decomposition problem’ encountered within the context of the stability analysis of thin-walled structural members is presented. The proposed method achieves decomposition of a randomly deformed shape into a number of constituent modes, which have the physical meaning of the classical local, distortional and global buckling modes, augmented with two additional classes of shear and transverse extension modes. The basis vectors of these five classes are created by defining sets of nodal forces which, when applied to the member in a first order linear elastic problem, generate shapes commensurate with specific mechanical criteria defining the local, distortional, global, shear and transverse extension modes. In a second step the basis vectors of a given class are used to define a constrained stability problem, where the solution is restricted to a linear combination of these basis vectors, in order to obtain the buckled shapes under a given loading. The full set of buckling modes spanning the five classes forms an orthonormal basis of the complete deformation space. Consequently, decomposition can be achieved by projecting the shape which is to be decomposed onto the basis vectors. Two examples are provided to illustrate the method.

ABSTRACT: This paper examined the effect of numerical modelling parameters on the accuracy and computational efficiency of Carbon Fibre Reinforced Polymer (CFRP) stiffened panels under Compression After Impact (CAI). Pristine and damaged CFRP stiffened panels were subjected to compression in Abaqus® software using Cohesive Zone Model (CZM) method. Various case studies were examined and the effect of the stiffness parameters of the cohesive elements was critically assessed. Moreover, the required number of cohesive zones to fully capture the damage mechanisms of the impacted and pristine panels under compressive loading was examined. The results showed that a wrong set of parameters can even lead to neglecting the induced damage and can cause severe convergence problems in the numerical model. The importance of the Overall Meshing Factor (OMF) was highlighted and a user-defined subroutine (USDFLD) was applied to capture the decrease in the load bearing capability of an impacted panel prior to the compressive loading, since CZM was found insufficient for this scope. The above-mentioned remarks illustrated the process of investigating the optimum numerical parameters set to achieve an accurate and efficient finite element modelling of the stiffened panels structural performance and maximum load-carrying capability, when subjected to CAI loading.

ABSTRACT: Nonlinear dynamic stability investigations for isotropic and composite cylindrical shells under pulsating axial loading are carried out through Finite Element analysis using numerical time integration. In particular, important characteristics of the geometrically nonlinear behaviour are systematically studied through Finite Element analysis. The results of the Finite Element analysis are compared with results obtained in earlier studies using semi-analytical procedures. In order to facilitate the evaluation and the comparison of these two complementary approaches, a modal projection procedure has been developed for the Finite Element analysis. Critical dynamic loads and frequency-response curves for isotropic and composite shells under pulsating loading obtained with the Finite Element analysis using numerical time integration are shown to be generally in good qualitative agreement with the results of earlier semi-analytical work. The analysis of the modal amplitude achieved via the modal projection procedure also makes it possible to study the interactions between...
contributing modes and to observe and interpret interesting phenomena such as the occurrence of travelling waves in the circumferential direction of the shell.

ABSTRACT: The goal of this paper is twofold. The first goal is to show that geometrically exact beam finite elements can be successfully employed to determine, accurately, the behaviour of steel I-section beams undergoing large displacements and finite rotations. For this purpose, a two-node geometrically exact beam element is presented and validated, which can handle arbitrary initial configurations (e.g. curved configurations), plasticity, geometric imperfections and residual stresses. The second goal is to employ the proposed element to assess the behaviour of I-section beams undergoing lateral-torsional buckling. In particular, the element is used to determine (i) elastic non-linear bifurcation loads (i.e., bifurcation loads accounting for pre-buckling deflections), (ii) large displacement elastic post-buckling paths including geometric imperfection effects and (iii) large displacement elastoplastic equilibrium paths accounting for geometric imperfections and residual stresses. Three support/loading cases are examined, namely: (i) simply supported beams under uniform moment, (ii) simply supported beams subjected to a mid-span vertical force and (iii) cantilevers subjected to a free end vertical force. Besides I-sections with standard height-to-width ratios, wider flange sections are also considered and it is demonstrated that, for the latter, the post-buckling behaviour is quite different from that of standard sections and an increase in the load carrying capacity is observed, which is not predicted by the current Eurocode 3 [1] provisions. Based on the results obtained, a set of relevant conclusions are drawn.

ABSTRACT: The evaluation of residual stress and its redistribution under cyclic loads are crucial to guarantee the integrity of welded components. In this paper, the effective parameters on welding residual stress relaxation are examined in thin cylindrical vessels due to cyclic pressure. First, the 3D finite element modeling is performed to evaluate the welding residual stress under cyclic pressure with various amplitudes and cycle numbers. Further, the model is verified using experimental stresses through the hole-drilling method. To study the plasticity behavior, two plasticity models are implemented: perfect plasticity and combined isotropic with kinematic hardening. It is concluded that the former leads to greater stress change. In addition, cyclic pressure causes redistribution and even change in the sign of the residual stresses, but this effect can be manifested as either stress relaxation or stress enhancement, depending on the initial residual stress. Moreover, the influence of various geometrical and loading parameters on stress modification is investigated through the Taguchi method. Statistical analysis reveals that an increase in thickness and diameter leads to a higher modified hoop stress, while an increase in maximum pressure leads to a lower modified hoop stress. On the other hand, the modified axial stress increases with an increase in thickness, and decreases with an increase in diameter. Analysis shows that thickness and maximum pressure are the most important parameters on the modified hoop and axial residual stresses, respectively. Finally, useful equations are proposed that can be used to calculate the modified residual stresses in terms of design factors.

ABSTRACT: The main structure of the central detector at the Jiangmen Underground Neutrino Observatory (JUNO) is a spherical shell structure, which has a giant acrylic spherical shell connected to a stainless-steel (SS) reticulated shell with 590 SS rods. The acrylic spherical shell is submerged into water and filled with detection liquid and prone to rotation subjected to considerable buoyancy. The stability against rotation of this super-deep underground spherical shell structure needs to be fully investigated. In this study, an effective and practical method consisting of parametric analysis and optimization procedure is proposed to improve the stability against rotation. Specifically, two indicators, namely, the critical loading multiplier and the rotation angle, are proposed to evaluate the stability against rotation of the acrylic spherical shell in linear and nonlinear stability analyses, respectively. Then, parametric analysis is performed to assess the sensitivity of the stability against
rotation to four parameters of interest (i.e., rod outer end constraints, liquid level difference, disc spring stiffness, and rod deviation). Based on the obtained parametric analysis results, the liquid level difference and disc spring stiffness are finally selected as design variables for the subsequent optimization process to further improve the stability against rotation. An efficient scheme combining design variable discretization and exhaustive method is adopted to identify the optimal variable values at which the acrylic spherical shell has good stability against rotation. The results indicate that the proposed method is efficient and effective for optimization of stability against rotation of such super-deep underground spherical shell structure. The proposed method is practical and easy to use for structural designers, and provides an efficient approach to the stability design of such rod-connected spherical shell structures.

ABSTRACT: Tanks, silos, and most large steel-shell structures consist of smaller pieces connected together during the manufacturing process. This causes several types of malformations on the shell walls. Furthermore, thin-walled members can be easily deformed in wall surfaces owing to the thickness of the structure. Fourteen thin-walled cylindrical shell specimens in two groups with different dent depths and various longitudinal dent numbers subject to hydrostatic pressure were tested in the present work. The models were designed to demonstrate how repairing dents by using carbon-fibre-reinforced polymer can recover lost capacity. The results of testing under different theories and codes were compared. This study shows the decreasing effects of the longitudinal dent number on the buckling capacity of the shells. Using carbon-fiber-reinforced polymer strips resulted in softening or stiffening behaviour in the models. Furthermore, to obtain the initial and overall buckling according to theoretical formulas, coefficients were predicted to obtain the initial, overall, and collapse buckling without an experiment for the models that were beyond the scope of the theories.

ABSTRACT: A unified analysis model for vibration characteristics of composite laminated annular sector plate, circular sector plate, annular plate and circular plate with various elastic boundary conditions is established based on the simplified plate theory (SPT) and two-dimensional (2D) improved Fourier-Ritz method. It has significant advantages in the study of free and forced vibration of thin-to-moderately thick rotary composite laminated plates. Under the current framework, the displacement admissible functions of the rotary plate are generally expressed as superposition of simple periodic functions, which includes the multiplication of two cosine functions and two complementary polynomials. The introduction of these polynomials can effectively eliminate jumping or discontinuity at the boundaries. The vibration characteristics of the rotary plate can be obtained by Rayleigh-Ritz energy technique. The present method shows fast convergence and good accuracy. The parameterization study on geometric parameters, material parameters and boundary conditions has been carried out to systematically reveal the vibration characteristics of rotary composite laminated plates, which can be the benchmark for the future research.

ABSTRACT: High-strength square concrete-filled double steel tubular (CFDST) slender beam-columns with a circular internal steel tube subjected to eccentric loads may undergo interaction local-global buckling. No computational studies on the interaction local-global buckling of slender square CFDST beam-columns have been reported and their behavior has not been fully understood. This paper describes a mathematical model for the simulation of the interaction local-global buckling behavior of square high-strength CFDST slender beam-columns under axial compression in combination with uniaxial bending. The mathematical model is formulated by the fiber approach, accounting for confinement provided by the internal circular steel tube, and geometric and material nonlinearities. An incremental-iterative numerical procedure is designed to quantify the local-global interaction buckling responses of slender CFDST columns. Efficient numerical solution algorithms implementing the inverse quadratic method are developed for solving the nonlinear equilibrium dynamic
functions of CFDST columns. The formulation proposed is verified by existing experimental data on CFDST columns as well as double-skin concrete-filled steel tubular (DCFST) slender columns. The developed computational model is employed to study the local-global interaction buckling behavior of CFDST columns made of high-strength materials with various important parameters. Simplified design models are proposed for determining the ultimate axial strengths of slender square CFDST columns under axial compression and the interaction curves of CFDST slender beam-columns loaded eccentrically. It is demonstrated that the computational and design models predict well the interaction local-global buckling behavior and strength of slender square CFDST beam-columns.

ABSTRACT: Laminated composite plates and shells have been widely used in aeronautical, mechanical, and naval structures. Stability is a major concern in the design of these structures due to their high slenderness. Therefore, it is necessary to properly analyze their post-critical behavior, assessing their sensitivity to initial imperfections and load-carrying capacity. This paper presents a methodology based on the Isogeometric Analysis to study the stability of laminated plates and shallow shells. In this formulation, the geometry and displacement field are described using NURBS basis functions. Appropriate integration schemes are used to avoid the locking problem for thin-walled plates and shells. The proposed formulation was applied in the stability analysis of various examples and excellent results were obtained. The influence of the composite layup and geometric imperfections on the buckling load and post-critical behavior is studied. New bifurcation solutions to a well-known laminated shell buckling benchmark problem are presented.

ABSTRACT: In this study, the axial impact behavior of empty and filled nested tubular structures is parametrically investigated both experimentally and numerically. The experiments are conducted by a drop test machine and the numerical studies are conducted using LS-DYNA software. The tubes are made of AL6063 aluminum alloy and a regular hexagonal honeycomb filler of ABSplus plastics. The external sizes of all specimens are held constant for meaningful comparisons. The primary objective of this study is to investigate the effects of using a honeycomb filler, increasing the numbers of tubes, and changing the lengths of the tubes on the nested tube structures. The results of single, double, triple, quadruple, and quintuple tubular structures, with and without the honeycomb filler, are compared in terms of collapse mechanism and common crashworthiness indicators, namely, peak crash force, specific energy absorption, and crash force efficiency. The results indicate that the honeycomb filler has a significant effect on the collapse mechanism of single and nested tubular structures, and the filled nested tube systems with fewer tubes are better than empty ones in terms of specific energy absorption and crash force efficiency. In addition, the energy absorption of the nested tubes could be increased in certain cases with the increase in the number of tubes and tube lengths increasing from the innermost to outermost tubes. Therefore, the double nested tube structures with a honeycomb filler are recommended for crash box designs.

ABSTRACT: This paper discusses the strength and stability of cold-formed welded hollow sections with and without stiffeners, as well as four different cross-section shapes, in terms of the “Overall Interaction Concept” (OIC). The studied types of cross-section are employed in various fields of the construction sector, and particularly in racking systems, where weight minimization is a specifically emphasized design objective. The scope of the study consists of an extensive experimental campaign, coupled with a comprehensive series of numerical tests. The results shown were developed in the framework of the European (RFCS) research project HOLLOSSTAB. The discussion of the results in terms of the OIC approach highlights its potential as a general
method for the cross-sectional design for hollow sections of various shape, loaded in various combinations of compression and bending.

ABSTRACT: Open-sections are often used in structural applications because of their material efficiency in providing members of high strength and stiffness. Although previous research has made significant progress in accounting for the effects when the shear-center and centroid are not coincident for such sections, the compression buckling strengths of non-symmetric sections, for example unequal-leg angles, are sometimes over- or under-predicted. This paper improves existing beam-column line-element formulations for accurately simulating the axial buckling behavior of arbitrarily-shaped open-sections. Detailed derivations are given and implemented within the educational software MASTAN2. Several verification examples are provided.

ABSTRACT: The paper presents results of the numerical and experimental study into crashworthiness performance and energy absorption capability of thin-walled square section columns with dents, subjected to axial impact load. Thin-walled aluminum tubes with four dents in the corners are under investigation. Energy absorption effectiveness of energy absorbing thin-walled structures is discussed. Finite Element parametric study into energy absorption capacity of structures under investigation is performed. Crushing behavior and some crashworthiness indicators are examined. Results of experimental impact tests carried out on aluminum tubes with dents of selected shape and position are presented. FE theoretical model and numerical results are confronted with those obtained from experimental tests. Some conclusions concerning optimal dent shape and position are derived.

ABSTRACT: Additive manufacturing, commonly known as 3D printing, is an evolutionary technology in the manufacturing industry. This technology has already been embraced by different industries, such as aerospace and biomedical engineering, and the recent advance in this technology has generated a vast of societal excitement for its future. Despite the exciting prospect of its application in civil engineering, additive manufacturing technology is still at a perceived stage for construction industry. The benefits and potential in construction industry are rarely known in the field at this stage. This paper aims to investigate the mechanical properties and structural performance of additively manufactured high strength steel tubular sections at the cross-sectional level through experimental program. The specimens were additively manufactured from H13 steel powder by selective laser melting (SLM) with three different scanning patterns, where the typical yield strength (0.2% proof stress) of the conventionally manufactured H13 steel is around 1650 MPa. The test program comprised tensile coupon tests, compression coupon tests, hardness tests, microstructural characterization as well as geometric imperfection measurements and stub column tests. The anisotropy on mechanical properties was examined through tensile coupon tests in both longitudinal and transverse directions. Compression coupon tests were also conducted to investigate the differential strength of material in tension and compression. The influences of scanning patterns on mechanical properties and structural behavior of as-printed high strength steel tubular sections stub columns were also investigated. The test results were used to assess the applicability of existing design provisions in the American Specification, Australian and New Zealand Standard

ABSTRACT: This paper presents a new logarithmic higher order shear deformation theory (LHS-DT) based on isogeometric analysis (IGA) to study the static bending, free vibration, and buckling behaviors of functionally graded plates. The temperature change conditions are considered. In the LHS-DT fashion, shear stresses disappear at the top and bottom surfaces of the plates and shear correction factor vanishes. The requirement for C-continuity in terms of the LHS-DT is straightforwardly possessed with the aid of inherent high order continuity of non-uniform rational B-spline (NURBS), which serves as basis functions in our IGA formulation. The superior performance and accuracy of the proposed method is demonstrated through extensive numerical examples. The computed results of static bending, vibration and buckling from the proposed theory are in a very good agreement with reference solutions available in literature obtained by various plate theories and different solving method.

ABSTRACT: This paper proposes a novel polyurethane foam-filled energy absorption connector with advanced geometry to dissipate energy. Quasi-static loading tests of these connectors were first conducted to evaluate failure mechanisms and energy absorption performances. Numerical and analytical models which exhibited...
results consistent with those of the experiment were developed to predict and conduct an in-depth study of the energy absorption characteristics. The results revealed that most energy absorption parameters could be enhanced by filling polyurethane foam, increasing the armed plate thickness, and decreasing the height from the top of the armed plate to the intersecting point of the two arms. The findings from this work help understand the failure mechanism and energy absorption behaviour of the proposed connectors, and they will promote potential applications of these connectors in terms of dissipating blast or impact energy.

ABSTRACT: This paper investigates the nonlinear buckling and postbuckling of functionally graded porous circular cylindrical shells reinforced by orthogonal stiffeners resting on Pasternak elastic foundations in thermal environment and under torsional load by an analytical approach. Shells are reinforced by closely spaced stringers and rings in which material properties of the shell and the stiffeners are assumed to be continuously graded in the thickness direction. Basing on the classical shell theory with von Karman geometrical nonlinearity and smeared stiffeners technique, the governing equations are derived. Using the Galerkin method with the three-term solution of deflection, the closed form to find critical load and post-buckling response are obtained. The effects of porosity coefficient, material, temperature, dimensional parameters, stiffener and foundation are analyzed.

Wanshi Hu, Harsh Bohra, Eyas Azzuni and Sukru Guzey (Lyles School of Civil Engineering, Purdue University, West Lafayette, IN, 47907, USA), “The uplift effect of bottom plate of aboveground storage tanks subjected to wind loading”, Article 106241, Thin-Walled Structures, Vol. 144, November 2019, https://doi.org/10.1016/j.tws.2019.106241

ABSTRACT: Because aboveground storage tanks are usually empty during construction, inspection and repair periods, they are more vulnerable to buckling due to wind loading than they are in use filled with liquid product. The uplift effect of the bottom plate of empty storage tanks due to wind pressure is investigated in this work. The buckling behavior of two sets of tanks were studied using finite element analysis (FEA): (1) tanks with bottom plate modeled directly in the analysis and (2) tanks without bottom plate but suitable boundary conditions applied in the analysis. Linear bifurcation analysis (LBA) and geometrically nonlinear analysis including imperfections (GNIA) are performed to obtain the deformation shapes and buckling capacities of tanks. The soil supporting the with-bottom tanks were modeled using nonlinear compression only springs connected to each node of the bottom plate. The buckling modes and the results from GNIA show that when a bottom is included into a tank FEA simulation, instead of fixed, the buckling pressure load will be substantially reduced for slender tanks having height to diameter ratio greater than 1/3. However, the broad tanks having height to diameter ratio less than 1/3 experience relatively small reduction in buckling load.

ABSTRACT: This study investigates buckling behaviors of functionally graded carbon nanotube-reinforced composites (FG-CNTRC) shells using a modified first-order enhanced solid-shell element formulation. On that account, a parabolic shear strain distribution through the shell thickness in the compatible strain part is proposed. In fact, the shear correction factors are no longer needed. Five kinds of single-walled carbon nanotubes (SWCNTs) distribution through the thickness of layers are considered, namely, uniform (UD) and functionally graded (FG) symmetric and asymmetric. The buckling behavior of FG-CNTRC plate under uniaxial compressive pressure and FG-CNTRC cylindrical shell under external pressure and axial compression are considered. Comparisons of our numerical results with those reported by other investigators are presented in
order to compare different formulations and to illustrate the performance of the developed solid-shell element. The result of the buckling behavior of CNTRC structure makes the present formulation appropriate for a wide range of structure plates and shells. Then, the effects of some geometrical and material parameters on the critical buckling load of shell structures are investigated.

ABSTRACT: Current investigation deals with the small and large amplitude free vibrations of a curved beam (arch) resting on a nonlinear elastic foundation. The arch is made of a functionally graded material, where the properties are graded across the thickness. Uniform temperature elevation in the arch is also considered and material properties are assumed to be temperature dependent. The governing motion equations of the arch are established using a higher order arch theory which satisfies the traction free boundary conditions and the von Kármán type of non-linearity. The governing equations of the arch are solved for the case of an immovable pinned arch using the two step perturbation technique. Closed form expressions are given to estimate the nonlinear frequencies of the arch as a function of the mid-span deflection. Numerical results of this study are validated for the case of flat FGM beams on elastic foundation. Afterwards, novel numerical results are given to explore the influences of power law index, elastic foundation coefficients, length to thickness ratio, length to radius ratio, and the temperature effects.

ABSTRACT: The study aims to investigate the effects of origami morphology and interval distribution on the mechanical behavior of origami-based and conventional tubes. Quasi-static axial crushing experiments have been conducted on six geometrical types of polymeric tubes with different morphology (including arrangement and patterns), uniform and non-uniform interval. The polymeric tubes having viscoelasticity are fabricated through a polymer blow molding approach, in which, the approach can ensure the integrated formation of these tubes and avoid the structural asymmetry caused by the machining process. The experimental results show that it is convenient to observe the collapsed position, plastic hinges, and collapsed modes from the crushed and incompletely recovered shapes of the polymeric tubes after 24-h unloading. The initial elastic stiffness and initial peak force of the origami-based tubes reduce dramatically as compared with those of the conventional tubes under the axial crushing. In addition, the origami morphology and interval distribution can cause the initial collapse and have a large effect on the final collapsed mode of the tube, while the effect of wall thickness on the collapsed mode can be negligible. Therefore, the origami morphology or non-uniform interval distribution of the origami-based tubes can be used as a geometrical defect to change the collapsed mode and as a trigger to orient the initial collapse in a certain position of the tube in engineering design.

ABSTRACT: This article presents a novel method to improve energy absorption performance of thin-walled circular tubes under quasi-static lateral loading through the preforming process. Desirable investigations are carried out by experimental tests and numerical simulations. Firstly, simple circular tubes are shaped into four different types (P1–P4) of preformed specimens, using a semi-cylindrical Teflon die and various blade-shaped indenters with semi-cylindrical nose. Then, the preformed specimens are laterally compressed between two rigid platens to perform flattening tests and their mechanical behaviors are investigated during the lateral flattening experiments, based on viewpoint of energy absorption. Some experiments are carried out and due to the test limitations, numerical simulations are performed, using the ABAQUS/Explicit software. In the following, based on the finite element analysis, various preformed specimens with different geometrical characteristics are simulated to investigate influences of wall thickness, preformed type and internal span of the specimen cross-section and also, effects of loading direction on energy absorption performance of the preformed specimens. Also, some simple circular tubes are flattened as the benchmark and results of four types of the preformed samples are compared with the corresponding benchmark. The obtained results illustrate that by shaping the simple circular tubes into the preformed specimen, a new hollow prismatic samples are produced that their energy absorption capability is 11.5 times of the corresponding value of the benchmark; consequently, the present article suggest the preformed specimens of various types instead of the corresponding simple circular tubes, as better energy absorber.

ABSTRACT: In this paper, the elevated temperature buckling performance and design of cold-formed square, rectangular and circular hollow section columns made of stainless steel is studied through a numerical modelling investigation. The finite element analysis software Abaqus was employed to perform the simulations, where the validity of the models was established by replicating the results of flexural buckling tests at both elevated and room temperatures from literature test programmes. In total, twelve square (SHS) and rectangular (RHS) hollow section columns tested at elevated temperature and eleven circular (CHS) hollow section columns tested at room temperature were simulated. Following this, a comprehensive numerical parametric investigation was performed to systematically assess the effect of variation of the governing parameters including the grade of stainless steel (austenitic, duplex and ferritic) and the elevated temperature member slenderness (Lambda=0.1–2.0) for all considered cross-section shapes with the addition of the aspect ratio of the cross-section (h/b=1.0 and 1.5) and the column axis of buckling (major and minor) for the SHS and RHS. The applicability and accuracy of the design methods recommended in EN 1993-1-2 and the Design Manual for Stainless Steel Structures were carefully assessed on the basis of the numerical flexural buckling performance results. New buckling formulations for the fire design of cold-formed stainless steel SHS/RHS and CHS columns were proposed, and their suitability was confirmed by means of reliability analysis.

ABSTRACT: In this study, a theoretical model is developed to reveal the bending collapse of top-hat thin-walled structures by dividing a top-hat thin-walled structure into a top-hat element and flat-plate element. A theoretical formula is also developed to describe the bending deformation and energy-absorption of the structures. The theoretical model is capable of predicting the bending collapse and energy-absorption of top-hat
thin-walled structures with different thickness and material specification. The accuracy and generality of the theoretical prediction model is validated by performing three-point bending tests and finite element simulations. Then, both theoretical prediction formulas and finite element analysis (FEA) based surrogate models are employed to perform the crashworthiness optimization of top-hat thin-walled structures. The results show that (i) the theoretical prediction model is capable of producing results that can be directly used to optimize the thicknesses, cross-sectional geometry, and material specifications for top-hat thin-walled structures, which will increase the efficiency and shorten the cycle time of crashworthiness design optimization for this type of structure; and (ii) steel-aluminum hybrid top-hat thin-walled structure has a larger energy-absorption capacity than high-strength steel without exceeding the initial weight, whereas a lightweight design is more feasible with an aluminum alloy than with high-strength steel without sacrificing the energy absorption of the baseline design.

ABSTRACT: A new type of composite shear wall, composed of dual steel plates, vertical stiffening steel plates to connect the dual plates and concrete infilled in the vertical channels formed by these steel plates, is proposed. Fifteen specimens were tested under horizontal cyclic loads, along with a constant vertical axial force, to investigate their seismic behaviour. Specimen failure mainly included three modes: severe local buckling at the corners of the flange plates and boundary channels, damage of the concrete occurring in the middle and bottom of the shear wall and local buckling waves originating at the middle of the specimen. All the specimens exhibited a good deformation capacity: the ultimate drift ratios of the specimens reached an average value of 4.55%, and the ductility has an average value of 4.0. The test results indicated that the thickness of the shear wall and the number of channels in the shear wall have a significant effect on the ductility of the specimens. However, changing the number of channels in the walls has a negligible effect on the shear strength of the wall. Formulas to predict the maximum shear strength and initial stiffness of the shear wall are proposed, and it is verified that they can provide a satisfactory prediction for most specimens, with an error within 10%.

Ashkan Babazadeh and Mohammad Reza Khedmati (Department of Maritime Engineering, Amirkabir University of Technology, No. 424, Hafez Avenue, Tehran, 15916-34311, Iran), “Semi-analytical simulation of plastic collapse mechanism of cracked continuous unstiffened plates used in ship structure under in-plane...
ABSTRACT: The present study is undertaken based on a nonlinear finite element study carried out by the same authors for estimation of ultimate strength of cracked continuous unstiffened plates used in ship structures under in-plane longitudinal compression. Investigations show that in addition to the magnitude of ultimate strength, the deflection shape and plastic collapse mechanism will also change completely. Results show that deflection in the cracked half wave increases more rapidly than other half waves. Consequently generated half waves in a cracked plate will not have identical length and amplitude. This implies that the conventional plastic collapse mechanism cannot be used to predict the behavior of cracked plates in the post ultimate strength region. A new plastic collapse mechanism based on the FEM results is suggested and the principle of virtual work is used to derive the axial stress-deflection relation of the plate. However, due to inequality of the length and amplitude of generated half waves, the axial stress-deflection relation cannot be directly derived from the principle of virtual work. Therefore, in order to solve the virtual work equation, some auxiliary relations between the involved parameters are required. Auxiliary equations are derived using regression analysis based on FEM results. Finally, a semi-analytical formulation is derived to estimate post ultimate strength behavior of cracked plates. It is shown that the proposed semi-analytical formulation can predict both magnitude and slope of the stress-deflection curves with better accuracy compared to the conventional plastic collapse mechanism. The formulation can be used within the defined ranges of simulated crack lengths, slenderness and aspect ratios.

ABSTRACT: This paper reports the results of an investigation on the use of Generalised Beam Theory (GBT) to assess the buckling behaviour of steel cylindrical shells (pipes, tubes and pressure vessels) acted by combinations of axial compression and external lateral pressure. Initially, the derivation of an adequate GBT formulation is addressed. It (i) incorporates all the effects stemming from the presence of longitudinal and/or hoop stresses (the latter act in the circumferential direction), and (ii) takes into account the destabilising influence associated with the follower nature of the external pressure, which remains normal to the shell wall along the deformation process. Then, after numerically implementing the above formulation, by means of GBT-based beam finite elements, its application and capabilities are illustrated through the presentation and discussion of numerical results concerning the buckling behaviour of (i) pressure vessels and pipes acted by external pressure and (ii) tubes subjected to combinations of compression and external pressure. For validation purposes, most GBT results are compared with values either available in the literature or yielded by Ansys shell finite element analyses.

ABSTRACT: The initial geometric imperfections in manufacturing structure are unavoidable. Critical buckling load and dynamic instability of the rotating cantilever cross ply laminate thin walled twisted plate with exponential function type initial geometric imperfection are investigated for the first time. The mode shapes are
obtained by using Rayleigh-Ritz method and shallow shell theory including the influence of rotational speed and imperfection. Based on the Lagrange equations and the obtained mode shape function, motion equations considering the first three modes of the system are derived. The mode shapes, critical loads and dynamic instability obtained in present have been verified by comparing them with other researcher results. The detail studies about the effect of rotating speed, twisted angle, stacking sequence and imperfection factors of the rotating thin walled twisted plate subjected to the in-plane load on the static critical buckling load and dynamic instability are carried out.

ABSTRACT: The partial CFRP (carbon fiber reinforced polymer) wrapping scheme is widely used for strengthening engineering practices to obtain a moderate improvement in strength, whereas detailed investigations on partially CFRP-wrapped thin-walled circular normal-strength concrete-filled steel tubular (NCFST) stub columns are seldom presented. This paper aims to conduct a series of numerical analyses to figure out the axial compressive performance of circular NCFST stub columns wrapped by CFRP belts partially. A nonlinear finite element (FE) modelling focused on the surface interaction as well as the CFRP and thin-walled hollow steel section (HSS) confinement effects on the concrete infill is developed via ABAQUS solver and the accuracy is validated against the existing experimental data. Following this, a systemic parametric investigation is developed to explore the impact of steel yield stress, concrete compressive strength, diameter: thickness ratio, CFRP wrapping ratio and number of CFRP layer, etc. on the axial compressive properties of the partially CFRP-wrapped thin-walled circular NCFST stub columns. Elaborate investigations on the surface contact action, stress-strain response, typical axial force versus axial shortening curve and failure modes are presented to better figure out the axial compressive behaviour of the type of composite column. A discussion on the effective wrapping scheme of the partially CFRP-wrapped thin-walled circular NCFST stub column imposed with axial compressive force is described as well. Finally, two types of design formulas in compliance with the unified theory and the tubed concrete method are proposed to assess the axial compressive resistance of the partially CFRP-wrapped thin-walled circular NCFST stub column. The research may provide a considerable and scientific basis for employing CFRP materials for the CFST structures.

ABSTRACT: The grouted T-joint in offshore structure is usually subjected to low-velocity impact caused by ship collision. The behaviour of these joints under lateral impact loading is investigated. Tests on 12 specimens including eight grouted T-joints are conducted. The composite T-joint consists of grout-filled double-skin steel tubular chord and hollow steel section brace. The constant axially compressive load is applied along the axis of the composite chord and the impact load is applied along the axis of the hollow steel tubular brace. A finite element model is established and verified. The influences of various parameters on the T-joint behaviour are discussed.

Jianxun Zhang, Yang Ye and Qinghua Qin (State Key Laboratory for Strength and Vibration of Mechanical Structures, School of Aerospace Engineering, Xi’an Jiaotong University, Xi’an, 710049, China), “On dynamic response of rectangular sandwich plates with fibre-metal laminate face-sheets under blast loading”, Article 106288, Thin-Walled Structures, Vol. 144, November 2019, https://doi.org/10.1016/j.tws.2019.106288

ABSTRACT: This paper focuses on the analytical and numerical analyses to predict the dynamic response of fully clamped rectangular sandwich plates with fibre-metal laminate face-sheets and metal foam cores under blast loading. Based on the rigid-plastic material approximation with modifications, simple models are developed for the dynamic response of sandwich plates with fibre-metal laminate face-sheets. The so-called ‘bounds’ and the membrane mode solution for dynamic response of rectangular sandwich plates are obtained. The effects of the composite volume fraction, the ratio of metal layer strength to composite layer strength, relative density and relative strength on the dynamic response are discussed. The finite element calculation is carried out to study the dynamic response of the sandwich plates under blast loading. Good agreement is achieved between the analytical solutions and numerical results. This work provides the efficient method that reasonably captures dynamic response of the rectangular sandwich plates subjected to the blast loading.

ABSTRACT: The present paper reports a thorough experimental and numerical investigation into the compressive behaviour and load-carrying capacities of concrete-filled steel tube (CFST) stub columns with the outer tubes made of a newly developed high-chromium grade EN 1.4420 stainless steel. In comparison with the most commonly used stainless steel grades EN 1.4301 and EN 1.4404, the new grade EN 1.4420 possesses lower material price, but better corrosion resistance and higher strength, and thus has a greater potential for widespread use in composite construction. In this study, an experimental programme was firstly carried out on 15 CFST stub columns with high-chromium stainless steel tubes of five different cross-section sizes and concrete infill of three grades, as well as 5 (reference) bare high-chromium stainless steel tube stub columns. The test setup, procedure and results, including the ultimate loads, load–deformation histories and failure modes, were fully reported. The experimental investigation was supplemented by a numerical modelling study, where the developed finite element models were firstly validated against the experimentally obtained results and then utilised to perform parametric studies for the purpose of expanding the limited test data pool over a wider
range of cross-section sizes. The test and numerical results were utilised to evaluate the applicability of the codified provisions, established in North America, Europe and Australia, to the design of the new concrete-filled high-chromium stainless steel tube stub columns. Overall, the examined design codes were generally found to yield safe-sided but slightly conservative resistance predictions for the new high-chromium stainless steel composite stub columns. Modifications to the codified design provisions were then made, and shown to result in an improved level of design accuracy.

ABSTRACT: K-span system double corrugated trapezoid sheet profiles are used in construction engineering as self-supporting arch roofs for buildings. Some cases of failures of such structures have been reported. Deep, transverse corrugations in the profile surface, formed as a result of manufacturing, make the use of standard designing methods difficult. The paper presents a scientific approach to determining the load-carrying envelope of double corrugated profiles under complex load. Tests are carried out on small fragments of individual profiles under simulated load and support conditions. The results of the tests indicate the significant influence of transverse notches on the formation of local instability, which results in a change of their geometric characteristics and profile load-carrying capacity.

ABSTRACT: Finite-element analysis (FEA) was performed in this study on the flexural behaviour of aluminium alloy circular hollow sections (CHSs) with circular through-holes subjected to gradient and constant bending moments. The non-linear finite-element models (FEMs) were established and verified by the corresponding experimental results. The material and geometrical non-linearities, as well as the initial geometrical imperfections, were taken into account in the FEMs. The validated FEMs were employed in an extensive parametric study on a total of 408 specimens, which have the cross-section slenderness ratio ($D/t$) and hole size ratio ($d/D$) ranged from 5 to 150 and from 0.2 to 0.8, respectively. The influences of the cross-section slenderness ratio and hole size ratio of the CHSs, as well as the quantity and location of the circular through-holes on the flexural strengths of aluminium alloy CHSs with circular through-holes, were carefully evaluated. The test and FEA flexural strengths are compared with the design flexural strengths determined by the modified direct strength method (DSM) and the modified continuous strength method (CSM) developed for aluminium alloy flexural members. The comparison indicates that the current design guidelines are conservative for aluminium alloy CHSs with circular through-holes in bending. Therefore, the design equations are proposed on the basis of the modified CSM for the flexural strengths of aluminium alloy CHSs with circular through-holes. A reliability analysis was carried out to evaluate the modified DSM, the modified CSM and the proposed design equations. It is demonstrated that the proposed design equations are of high precision and reliability for aluminium alloy CHSs with circular through-holes in bending.

ABSTRACT: The free vibration characteristics of the variable stiffness composite laminated plates containing embedded cutout of desired shapes is investigated. The circular, elliptical and quadrilateral perforation geometries are taken into account. In order to provide a strongly flexible calculation tool, an isogeometric
analysis formulation based on the non-uniform rational B-splines (NURBS) along with the Nitsche technique is developed based on the first order shear deformation plate theory. The effects of change in the mechanical properties of tow steered laminates throughout the geometry due to fibers following prescribed curvilinear paths are taken into account in the integration procedures. The accuracy and reliability of the calculations is shown through some representative comparisons. The effects of change in the cutout geometry, location and orientation in conjunction with the curvilinear fiber placement are studied.

ABSTRACT: Modern manufacturing processes and computational methods give the possibility to design shell structures with complex shapes. Such opportunity enables to use the structural advantages coming from their untypical geometries. In this paper the results of strength and stability analyses of a shell of revolution in the shape of Booth ovaloid are presented. The shell is proposed as an alternative for classical closed pressure hulls loaded with external pressure. The stress distribution along the meridian of the shell is provided as well as the buckling shapes, buckling loads and equilibrium paths. The influence of geometrical parameters of the lemniscate on the above mentioned results is discussed. The analysed shell is compared with the classical cylindrical pressure hulls as well as spherical shells, the advantages of the former are pointed out. Since the shape of the Booth lemniscate changes considerably depending on geometrical parameters it can be easily adopted to numerous applications.

ABSTRACT: Functionally graded structures are widely observed in nature and have been considered to have excellent mechanical properties. In this paper, a novel bio-inspired graded honeycomb-filled circular tube (BGHCT) is proposed to enhance structural energy absorption characteristics under lateral load. The graded honeycomb fillers are constructed using 3D printing techniques. To systematically explore the crashworthiness of BGHCT, the nonlinear finite element models are first developed in Abaqus (explicit) and validated against the experiments. Then graded honeycomb-filled circular tubes with axial and radial graded directions are compared with uniform honeycomb-filled counterparts (UHT). Parametric studies find that BGHCT exhibits superior capacity of energy absorption. Furthermore, various parameters, like effective filling length, thickness and yield stress of column wall, have a considerable effect on the crashworthiness of this novel structure. Lastly, multi-objective optimizations of BGHCT and UHT are carried out with the aim of simultaneously improving specific energy absorption (SEA) and reducing peak crushing force (PCF), based upon the Kriging modeling technique and non-dominated sorting genetic algorithm II (NSGA-II). The optimal design parameters are obtained for these honeycomb-filled structures. By comparison we find that energy absorption characteristics can be increased by up to 89.73%, and effective length filled structure has the best crashworthiness, followed by full graded honeycomb-filled structure. The study provides new insights into the transformation of natural biological inspiration into engineering applications for crashworthiness.

ABSTRACT: This paper firstly proposed steel-concretes-steel sandwich walls with J-hook connectors (SCSWJs) as protective structures in the Arctic offshore platforms. Followed, six large scale SCSWJs were tested under lateral cyclic loading to investigate their lateral seismic behaviours. The investigated parameters in
the testing program included spacing of J-hook, concrete core strength, thickness of steel faceplate, and aspect ratio. Seismic behaviours of SCSWJs were reported in details, and the effects of these parameters on their seismic behaviours were reported and discussed. The test results showed that the SCSWJ failed in flexure mode with characteristics of tensile yielding of side plate and steel faceplate, concrete crushing at the bottom toe, and outward local buckling of steel faceplates. Pinching effect was observed in the load versus lateral drift curves after the peak load due to premature local buckling of side plates and faceplates locating between the first and second row of J-hook from the bottom. This paper developed analytical models to predict the peak lateral resistance of SCSWJ. The validations against 12 results from six cyclic tests confirmed that the developed models offered reasonable but conservative predictions on the peak lateral resistance of SCSWJ. This study promotes the applications of the SCSWJ in the earthquake-prone Arctic regions.

ABSTRACT: According to the surface imperfections of rolling–welding cylinders, a finite element analysis (FEA) model for a cylinder with surface imperfections is proposed, namely, a statistic imperfections model. The maximum permissible geometry deviation values $e$ of statistic imperfections models are computed based on the shape reduced coefficient $\beta = 0.8$. Compared with the limited value of ASME Code sections VIII-1 and VIII-2, it is clear that the calculated value $e/t$ is positively correlated with the length–diameter ratio $L/D$ and diameter–thickness ratio $D/t$ and that the yield strength has a substantial influence on the maximum permissible geometry deviation values, which is not taken into account by Code VIII-2.

M.J. Khoshgoftar (Department of Mechanical Engineering, Faculty of Engineering, Arak University, Arak, 38156–88349, Iran), “Second order shear deformation theory for functionally graded axisymmetric thick shell with variable thickness under non-uniform pressure”, Article 106286, Thin-Walled Structures, Vol. 144, November 2019, https://doi.org/10.1016/j.tws.2019.106286

ABSTRACT: This paper studies Second order Shear Deformation Theory (SSDT), as a higher order shear deformation theory, for an axisymmetric functionally graded shell of revolution with variable thickness. According to symmetrical condition, there is not any displacement and any variation along the symmetric direction. The governing equations of proposed shell are derived by virtual work principle. As a special case, the governing equations are rewritten for a cylinder with variable thickness and non-uniform internal pressure. The comparison between current work, classical theory and First order Shear Deformation Theory (FSDT) are illustrated with some numerical results. Non-homogenous material, boundary condition effects, non-uniform pressure, arbitrary curvature with variable thickness and nonlinear displacement field are some advantages of current work. The optimum design of shell is the main goal of current approach that has a wide industrial application like aerospace engineering.

ABSTRACT: The combined loadings of the fragment impact and pool-fire caused by domino accidents in storage tank farms or oil depots can result in damage greater than that caused by a separate loading. However, due to the complexity of the combined loadings, these have not been well understood. In this study, the coupling effects of the fragment impact and adjacent pool-fire on the thermal buckling of a fixed-roof tank were numerically investigated. The effects of impact velocities, impact angles and fragment shapes on the failure mode and fire resistance of a fixed-roof tank were discussed. The results indicate that the coupling effects of the fragment impact and adjacent pool-fire were deeply different from those in which the fixed-roof tank was subjected to either fragment impact or adjacent pool-fire individually. The fire resistance and critical buckling temperature decreased for pre-damaged tanks comparing with no-pre-damaged tanks. Besides, the local buckling mode triggered by the adjacent pool-fire was depended on the impact dent zone caused by the fragment impact. Moreover, the fire resistance and critical buckling temperature reduced with the increase of
the impact velocity, structural stability of the fragment and the decrease of the impact angle. This study can be used to understand the vulnerability and obtain the critical failure criterion of the large storage tanks under the coupling effects of multiple accidents, and optimize the steel structure design of oil tanks for resisting projectiles and pool-fires in tank farms to reduce the possibility of storage tank accidents.

ABSTRACT: This paper aims to fabricate star polygon thin walled energy absorption structure that tends to relapse the intensity of set in decelerations during impact while escalating the amount of energy absorbed. The crashworthiness topology optimization is used for structural optimization of various foam-filled tubes. The relative advantages of 14 configurations are discussed, and the effects of filling five types of foam into the best configuration of the star-shaped tube over an empty one is investigated. Specific Energy Absorption, Peak Crush Force and response of weight of the members during frontal impact are the main dimensions parameters of the member's performance. Numerical simulation is carried out using the explicit dynamics of Ansys 17.1, and obtained results are compared with experimental results conferring crash behavior and energy absorption characteristics. Based on results, the suited configuration with required performance in crashworthiness is suggested, which shall be incorporated in automobiles for safety consideration of passengers during an impact. The results show an increment of 40% in Specific Energy Absorption suggesting a better choice of a particular type of foam over a hollow tube.

ABSTRACT: The use of cold-formed steel (CFS) channel sections are becoming popular as the load-carrying members in building structures, and such channel sections often include web openings for the ease of installation of services. Traditional web openings are normally punched, and are unstiffened which can restrict the size and spacing of web openings. Recently, a new generation of CFS channel sections with edge-stiffened web openings has been developed, and is widely used in New Zealand. However, no experimental investigation has been reported in the literature for such channel sections under compression. In this paper, a total of 75 results comprising 26 axial compression tests and 49 finite element analysis results are reported on the compression resistance of CFS channel sections with both edge-stiffened and unstiffened web openings. For comparison, channel sections without web openings were also tested. For all specimens, initial imperfections were measured using a laser scanner. A nonlinear elasto-plastic finite element model was also developed, and the results showed good agreement with the test results. A parametric study was conducted using the validated finite element model to investigate the effect of opening spacing and column length on compression resistance of channel sections. It is shown that for the case of a channel section having seven edge-stiffened web openings, the compression resistance increased by as much as 22%, compared to a plain channel section. For comparison, the same section having unstiffened web openings had a 20% reduction in compression resistance, compared to a plain channel section.

ABSTRACT: In this study, the postbuckling analysis of functionally graded graphene platelets reinforced composite (FG-GPLRC) cylindrical shells is presented. The continuous uniform and functionally graded distribution of GPLs is considered through the thickness direction of the shell. In order to present the effective mechanical properties of GPL-reinforced composites the modified Halpin-Tsai micromechanical model is taken into account. On the basis of first-order shear deformation shell theory and von Karman geometrically nonlinear relations, the nonlinear governing equations are present in the context of the variational formulation. Employing the Fourier series and variational differential quadrature (VDQ) numerical approach, the semi-analytical solution methodology is further presented. The pseudo arc-length continuation method in conjunction with a load disturbance approach was utilized to solve the nonlinear governing equations and trace the postbuckling path. Note that based on the proposed formulation, the mode changes and secondary buckling can be considered through the postbuckling path. The results indicate that in addition to geometrical parameters, distribution patterns and weight fractions of GPLs have significant effects on the buckling and postbuckling characteristics of FG-GPLRC cylindrical shells.

ABSTRACT: A complex structural system can be described by a collection of individual rigid and/or flexible components in combination with a set of kinematic constraints. Moreover, their configuration can be described by redundant coordinates yielding to singular system matrices. Therefore, the calculation of frequencies and modes using a classical modal analysis is not longer applicable. In this work, we propose a variational-consistent framework, which is able to deal with structural systems with singular matrices and relies on a null-space projection. Finally, the effectiveness of the proposed framework is tested successfully by complex examples (single- and multibody systems) containing rigid bodies, geometrically exact beams and solid-degenerate shells.

ABSTRACT: Free vibration characteristics of parallelogram laminated thin plates under multi-points supported elastic boundary conditions are studied by improved Fourier series method (IFSM) in this paper. The parallelogram thin plate region is first transformed into the unit square region. Artificial virtual springs are introduced to simulate various boundary constraints. In the study, to remove the jumps or discontinuities problem on the boundary, an IFSM is used to express all allowable displacement functions of parallelogram laminated thin plates. All energy equations of thin plates are established by the classical thin plate elasticity theory. Then the Rayleigh-Ritz method is used to solve the problem. The innovation of this paper lies in the combination of non-uniform boundary constraints and coordinate transformation. By comparing a large number of numerical results with the finite element method, the results show that the method has high stability, accuracy, and rapid convergence. Moreover, the parametric research of vibration characteristics of the parallelogram laminated thin plate is also studied. The method can easily obtain the free vibration peculiarities of parallelogram laminated thin plates under multi-points supported elastic boundary constraints, including its natural frequencies and modal shapes.

ABSTRACT: The Heat Treatment Forming and in-die Quench (HFQ) process allows for manufacturing of more complex geometries from Aluminium sheets than ever before, which can be exploited in lightweight automotive and aerospace structures. One possible application is manufacturing thin walled beams with corrugated internal reinforcements for complex geometries.

This work considers different internal reinforcements (C-section and corrugated) to improve the energy absorption properties of thin walled rectangular beams under uniaxial and biaxial deep bending collapse, for loading angles ranging from 0 to 90 deg, in 15° increments. Using LS-DYNA simulations experimentally validated through unreinforced metallic tubes under quasi-static bending collapse, the finite element results demonstrate the stabilising effect of the reinforcements and an increase in the buckling strength of the cross section.

Corrugated reinforcements showed a greater potential for increasing specific energy absorption (SEA), which was supported by investigating key geometric parameters, including corrugation angle, depth and number. This favourable response is due to an increased amount of material undergoing plastic deformation, which consequently improves performance of the beam undergoing post buckling and deep collapse. This concept is applicable to vehicle and aircraft passive safety, with the requirement that the considered geometries are manufacturable from Aluminium Alloys sheet only, using the HFQ process.

A new formula to predict buckling pressure of steel ellipsoidal heads under internal pressure

ABSTRACT: Buckling is a critical failure mode of ellipsoidal head under internal pressure. This study focuses on the prediction of buckling pressure of steel ellipsoidal heads subjected to internal pressure. First, finite element model of ellipsoidal head is generated, taking into account the effects of material and geometrical nonlinearity. The plastic bifurcation buckling pressure of ellipsoidal head is determined by nonlinear FEM. Second, we study the effects of diameter-thickness ratio, radius-height ratio, yield strength, strain hardening and attached cylinder on buckling pressure. Based on FE results of the models with elastic-perfectly plastic material, we propose a formula to predict buckling pressure of perfect ellipsoidal head. In addition, we summarize experimental results on the buckling of twenty-one ellipsoidal heads which cover different geometrical parameters, material types, and methods of fabrication. Eleven out of twenty-one ellipsoidal heads were tested by the authors recently. Finally, based on the formula for perfect ellipsoidal heads, a new formula is developed for the buckling pressure of actual ellipsoidal heads after considering a reduction factor that accounts for the effect of initial shape imperfection. The reduction factor depends on the methods of head fabrication, i.e. whether cold pressing and spinning or assembly of formed segments. It is shown that the new formula has comprehensive advantage in accuracy and applicability in comparison with other formulae.
This was done through numerical investigations followed by a parametric study which are reported herein in...
details. A wide range of roll-formed ALC sections covering web slenderness ratios ranged from 28 to 130, inside bent radii ranging between 2mm and 8mm, bearing lengths ranged from 50mm to 150mm, and three sheeting aluminium alloy grades (5052-H32, 5052-H36 and 5052-H38) were considered in the parametric study. The acquired web crippling database was then used to assess the consistency and accuracy of the current design rules used in practice. It was found that the web crippling capacity determined by the current international specifications are unsafe and unreliable, whereas the predictions of the recently proposed equations agree very well. Furthermore, a Direct Strength Method (DSM)-based capacity prediction approach was proposed and then validated against the web crippling database acquired here as well as the experimental and numerical data for cold-formed steel lipped channel sections used in the literature.

ABSTRACT: This paper is focused on the external thin-walled tube inversion using different die fillet radii and is aimed at analysing its formability limits by local buckling, necking and fracture in principal strain space. The investigation draws from a methodology that was recently developed by the authors for general tube forming and focuses on the specificities that characterize its application to the deformation conditions of external tube inversion. Strain loading paths and formability limits at the onset of buckling, necking and fracture are determined by combination of experimental strain analysis with digital image correlation (DIC), thickness measurements, force-displacement evolutions and finite element modelling. Results show the paramount importance of the curling radius on the formability limits of external tube inversion. This information is relevant for designing energy absorbers based on external tube inversion and the novelty of the paper stems from the use of experimental techniques commonly employed in metal forming to the analysis of formability and failure in typical deformation modes of energy absorbers.

ABSTRACT: Unitized curtain wall systems made of aluminium frame infilled glass panes are commonly used to form the building envelopes in many buildings. The vertical framing members of such systems known as mullions are extruded aluminium sections with complex geometries. These mullions must transfer the wind load acting on the building envelope to the main structural system. This paper presents a detailed numerical study on the member moment capacities of long span mullion sections subject to wind suction loading. Validated finite element models of the mullions developed to predict their section moment capacities were extended to predict the member moment capacities. The procedures adopted in developing the finite element models and the analysis results are given in this paper. Mullions of different cross-section geometries with varying member slenderness used in both the captive and structural glazing systems were considered. In addition, the performance of open and hollow mullion sections was investigated. Lateral restraints provided by the glass panels to the mullions were simulated in the models while the effect of providing lateral restraint at the mid-span of the mullion through bracing was also investigated. The finite element analysis results were compared with the predicted capacities of Aluminium Association Design Manual and Eurocode 9 Part 1-1 design rules and suitable recommendations were made in relation to their applicability for mullion sections. Improved mullion sections reinforced with cold-formed steel stiffeners were proposed and their potential use in real world applications was discussed.

ABSTRACT: The paper analyzed the free vibration of functionally graded porous spherical shell (FGPSS) based on Ritz method. The energy method and first-order shear deformation theory (FSDT) are adopted to derive the formulas. In this paper, the displacement functions are improved on basis of domain decomposition method, in which the unified Jacobi polynomials are introduced to represent the displacement functions component along meridional direction, and the displacement functions component along circumferential direction is still Fourier series. In addition, the spring stiffness method is formed a unified format to deal with various complex boundary conditions and continuity conditions. Then the final solutions can be obtained based on Ritz method. To prove the validity of proposed method, the results of the same condition are compared with those obtained by FEM, published literatures and experiment. The results show that the proposed method has advantages of fast convergence, high calculation efficiency, high solution accuracy and simple boundary simulation.

ABSTRACT: In the present work, the distortional buckling behaviour of simply supported columns and beams made from channel sections with longitudinal web ribs is investigated when subjected to axial compression and/or pure bending. The effect of stiffening ribs on the critical buckling stress of such members is studied using finite strip method (FSM). An analytical model, namely, the stiffened plate buckling model (SPBM), is developed. Based on this model, the closed form analytical solution is obtained and the formulae for calculating the critical distortional buckling stresses are derived. The analytical solution is then validated by comparing the critical distortional buckling stress with those obtained in finite strip method (FSM). An excellent agreement from the comparison is found. The present model has the potential to be adopted in the development of the designed model of such sections in engineering practices.

ABSTRACT: A novel theoretical method is developed to determine the snap-through boundaries of thin-walled plates under thermal and acoustic load. By accounting for the correlation between the acoustic load probability distribution and the extreme points of the stiffness curves, an analytic snap-through boundary is derived in the parameter plane of the buckling coefficient and the sound pressure level. The accuracy of this method is verified by finite element analysis and existing literature. The effect of influence factors was investigated in detail. This work should provide a basis for structural safety evaluation and design optimization.

ABSTRACT: This paper presents the results of an investigation concerning the influence of corners with standard radii in the local buckling behaviour of thin-walled rectangular hollow section (RHS) members subjected to combinations of axial force and biaxial bending. The calculation of the half-wave length leading to the minimum critical bifurcation load is performed by means of a Generalized Beam Theory (GBT) specialization, developed taking advantage of the assumption that the stress resultants are uniform along the member length. This assumption makes it possible to obtain semi-analytical solutions, adopting half-wave sinusoidal amplitude functions for the GBT cross-section deformation modes, and leads to a numerical implementation that (i) is able to quickly solve a large number of problems and (ii) provides physical insight into the critical buckling mode mechanics, through a shell-like stress resultant-based energy criterion, as well as the modal decomposition features of the GBT semi-analytical solutions. Members with cross-sections belonging to the EN10219-2 database are analysed and their critical buckling coefficients are compared with those provided by available analytical expressions and/or currently included in steel design codes, namely Eurocode 3 and the North American Specification for Cold-Formed Steel Members. Analytical expressions are developed to take into account the (usually) beneficial influence of the rounded corners to the RHS member critical buckling stress.

ABSTRACT: The reduction in the stress concentration factor (SCF) around a circular hole in an infinite panel by adding an isotropic functionally graded incompressible material (FGIM) lining is analytically investigated. We assume that the shear modulus varies only in the radial direction either as a power-law function or an exponential function. For a panel subjected to far field uniaxial tension, the problem is solved by superposing the solution of two independent problems – one of biaxial tension and the other of pure shear loading. The former has a closed-form solution and latter's solution is either closed-form or in the form of the Frobenius series which depends on the functional form of the shear modulus. We also study tailoring the FGIM shear modulus in the radial direction to achieve a desired value of the SCF. For the biaxial tension loading, the required shear modulus variation is explicitly obtained, but for the uniaxial tension loading the approximate variation is numerically found. Numerical results for a few example problems reveal that the SCF strongly depends upon the sign of the shear modulus slope at the hole periphery. The FGIM lining alleviates the SCF at the hole periphery and in some cases migrates the point of the maximum hoop stress to the panel interior. Thus not only the SCF but also the maximum hoop stress in the panel interior must be considered in the panel design. The analytical results presented here should serve as benchmarks for verifying the accuracy of approximate/numerical solutions for a panel with a circular hole.

ABSTRACT: This paper presents an efficient computation method for matrices in the isogeometric analysis (IGA) of laminated composite plates, based on the First order Shear Deformation Theory (FSDT). In the method, the stiffness matrix, mass matrix and geometric stiffness matrix for static, vibration and buckling analyses are adapted into tensor-product forms and 2D integrals of the matrices are decomposed into Kronecker product of 1D integrals, which leads to the improvement of computational efficiency. Several experiments that apply the method to the static analysis and design optimization of laminated composite plates are presented in this paper to demonstrate its effectiveness. The first experiment studies the case that the domain parameterization has a diagonal Jacobian matrix (rectangular plate), and the result shows that the computation
time of global matrices is drastically reduced while their accuracy is not affected compared with traditional computation methods. The second experiment is about the case of non-diagonal Jacobian matrix. The results of circular plate, annular plate and square plate with complicated cutout show that the matrices calculation is also remarkably sped up when its model is formed in NURBS. Although the tensor-decomposition incurs certain approximation in the second case, the results still show high accuracy. The third and fourth ones study the computation efficiency of design optimization, respectively about the constant-stiffness and variable-stiffness designs when the proposed method is applied to the analysis in each iteration. All the experiments prove the high efficiency of the proposed method.

ABSTRACT: It is known that the foam-filled tubes offer significant improvement in energy absorbing owing to the interaction between the foam filler and the tube wall during axial folding deformation. In this study, an experimental investigation was carried out to clarify the interaction. For this purpose, two main specimen configurations, namely uniform density foam-filled (UDF) and radially-graded density foam-filled (RGDF), were prepared by filling aluminium tubes with PVC foam (60 and 100 kg/m³) and tested under axial compression. The experiments revealed that application of radially-graded foam filling to the tube enhanced energy absorption capacity (EAC). EAC of the RGDF and UDF specimens were 48% and 40% higher respectively than that of the base tube. Moreover, the specific energy absorption (SEA) value for the RGDF filled tube was found as 23.8 J/g while it was 21.5 J/g for the UDF filled specimen. From the experimental results, two main influence effectively increased the absorbed energy such as the axial resistance of the foam filler and the squeezed foam between inward parts of tube folds. It was concluded that if a proper foam filling design is applied the contribution of the foam squeezed between inward tube folds would have a noticeable effect on the EAC with higher SEA.

ABSTRACT: This is the first research on the nonlinear vibration of smart viscoelastic composite doubly curved sandwich shell with flexible core and MR layers with different distribution patterns. By using Reddy's third order shear deformation theory (TSST), the strains and stresses are obtained. This smart model including multiscale composite layers, flexible core and magnetorheological layer (MR). According to the Halpin-Tsai model three-phase composites layers have been considered. The governing equations of the multiscale doubly curved shell have been derived by implementing the Hamilton's principle. For investigating correctness and accuracy, this paper is validated by other previous studies. The results of this work are validated through the comparison with the results available researches. Finally, the influence of different parameters such as temperature rise, various distributions pattern, magnetic fields, and curvature ratios on nonlinear frequency response are investigated in the details. The results presented that the multiscale doubly curved sandwich shell with flexible core show a complex behavior.

Han Huang and Shucai Xu (State Key Lab of Automotive Safety and Energy, Tsinghua University, Beijing, 100084, PR China), “Crashworthiness analysis and bionic design of multi-cell tubes under axial and oblique impact loads”, Article 106333, Thin-Walled Structures, Vol. 144, November 2019, https://doi.org/10.1016/j.tws.2019.106333

ABSTRACT: Creatures in nature adapt to the environment by a long-term evolution, they often obtain the optimization structures for hunting and self-defence. One such example is a marine crustaceans named Odontodactylus scyllarus (O. scyllarus) has hammer-like dactyl clubs, which can bear high-velocity impacts and absorb the impact energy efficiently. In this paper, a novel bionic multi-cell tube (BMT) with three layers of circular columns was designed, inspired by dactyl clubs structure of O. scyllarus. The crashworthiness of BMTs with different bionic-cell numbers were investigated under axial and oblique loads using nonlinear finite element (FE) method through LS-DYNA. Secondly, a complex proportional assessment (COPRAS) method
was used to select the best possible sectional configuration under multiple loading angles. According to this method, the BMT with five cells (BMT-5) was determined to be the best design based on multicriteria process. Finally, a metamodel-based multiobjective optimization method based on polynomial regression (PR) metamodel and multiobjective particle optimization (MOPSO) algorithm were employed to optimize the dimensions of the BMT-5, where $F_\text{cr}$ and $EA$ were taken as objectives and wall thickness $t$ and middle circle diameter $D$ regarded as the design variables. The multiobjective optimization results showed that the BMT-5 has variant optimal solutions under different single loading angles. The optimal solutions of mutliobjective optimization under the multiple loading angles was highly dependent on the selection of weighting factors for different loading cases. Further research is required to investigate the crashworthiness analysis of BMTs under lateral impact.

ABSTRACT: The fabrication of pipe bends using rotary pipe bending (RPB) process results in geometrical imperfections as described by cross-sectional ovality and wall thickness variations which affect the pipe bends performance during service. Previous studies whether ignores these imperfections (Ideal pipe bend (IB)) or assume these imperfections in their analysis (Assumed shape bend (AS)). The objective of the present work is to investigate, using non-linear finite element analysis, the effect of the residual stresses and the presence of the inherited geometrical imperfections (low ovality) obtained from RPB process of 90° pipe bends on their load carrying capacities as compared with the IB and AS models. RPB process with basic tooling configuration is first simulated to obtain the as-fabricated 90° pipe bend. The results of this step were verified against published experimental results and analytical solutions, and compensated for springback. The pipe bend was then subjected to different combinations of loads (in-plane moment and internal pressure) to construct a comparative limit load diagram. Within the scope of our study, results have shown that the presence of the residual stresses remarkably reduces the pipe bend load-carrying capacity. IB model results in non-conservative results as geometrical imperfections lower the load carrying capacity of the pipe bend, while the AS model has been found to be invalid for cases where a mandrel is used in RPB process.

ABSTRACT: In this study, an effective analytical solution for the stability problem of functionally graded (FG) carbon nanotube reinforced composite (CNTRC) conical shells (CSs) exposed to external lateral and hydrostatic pressures is presented. The materials of functionally graded carbon nanotube reinforced composite conical shells (FG-CNTRC-CSs) are graded in the thickness direction according to linear distributions of the volume fraction of CNTs. The effective material properties of CNTRC-CSs are calculated using the extended mixture rule. The basic equations of CNTRC-CSs are derived using modified Donnell-type shell theory based on the first order shear deformation theory (FSDT). By using Galerkin method, the expressions for the critical external pressures of FG-CNTRC-CSs are obtained. The accuracy and reliability of existing solutions is confirmed by numerical examples and comparison with the results based on the FSDT and classical shell theory (CST) in the literature. Finally, numerical calculations are performed to demonstrate the effects of various graded profiles and volume fraction of CNTs and variation of CSs geometry on the critical external pressures for FG-CNTRC-CSs.

ABSTRACT: Using energy principles, a thin-walled beam element is introduced for the analysis of beams with deformable cross-sections that are prone to distortion. The beam element is based on previously attained semi-analytical displacement solution modes of an advanced thin-walled beam model. The first-order beam element for linear analysis handles shear deformations related to both Timoshenko and Mindlin-Reissner type deformations, warping effects of torsion, cross-section distortion including associated warping effects, as well as the transverse displacement effect from normal stress. The formulation can handle both open and closed cross-sections without special attention. The formulation of the displacement solution modes and the stiffness integration of the products of the advanced displacement modes using the Hadamard product are described. The paper also presents the transformations between modal degrees of freedom and element displacement degrees of freedom. Four examples show the beam element capabilities and good agreement with results obtained using the shell and solid elements of a commercial finite element program. The kinematic assumptions that the thin-walled beam model accommodates leads to local shear stress transfer at corners. This transfer of shear stresses is not normally seen in thin-walled beam formulations or shell models. However, the shear transfer is verified through examination of a finite element model using solid elements.

ABSTRACT: This study investigates the lateral impact behavior of double-skin steel tubular (DST) members with ultra-high performance fiber-reinforced concrete (UHPFRC). A total of six specimens were prepared and tested under lateral impact loading. In addition to UHPFRC filled DST members, normal strength concrete (NSC) filled DST member was also tested for comparison. Other investigated parameters in this study include the impact energy, the outer steel tube thickness, the inner steel tube thickness, and the presence of axial force. The test results demonstrate that the UHPFRC filled DST members exhibit significantly higher lateral impact resistance capacity than the NSC filled DST member. The impact energy and the outer steel tube thickness significantly affect the lateral impact behavior of UHPFRC filled DST members, while the influence of inner steel tube thickness is insignificant. With the applied axial force in this study, the influence of axial force is also insignificant. Afterwards, numerical model was developed and validated by the present test results. Based on the validated numerical model, the mid-span bending moment distributions and the stress wave propagations were investigated. Finally, parametric analyses were carried out to investigate the influences of different parameters on the lateral impact behavior of UHPFRC filled DST members.

ABSTRACT: Using a two-dimensional (2D) metal sheet to design structures exhibiting different dynamic properties can show prolonged promising for actual engineering. In this study, a Miura tube is first designed and fabricated by using a five-step strategy. The structure is constructed by carefully stacking two identical brass Miura sheets into one tube. A finite element (FE) model with high-fidelity has been developed to predict the natural frequencies (NFs) of the Miura tube and simulation results have been compared with the data from experiments. The dynamic responses of the Miura tube are then numerically investigated by using the verified FE model. Finally, a multi-objective optimization strategy is developed to optimize the Miura tube in order to maximize the fundamental frequency and minimize the dynamic displacement simultaneously. Results show that the dynamic properties of the Miura tube, made from one same metal sheet, can be significantly altered in a wide range by simply changing its geometric parameters. Moreover, the proposed structure can be easily fabricated from a single thin sheet made of one material and simultaneously owns better mechanical properties than the Miura sheet.

ABSTRACT: An experimental research was conducted for the eccentric compression behavior of concrete-encased-and-filled steel tube (CEFT) columns with high-strength circular steel tube. Five eccentrically loaded columns and one concentrically loaded column were tested under monotonic axial compression. The parameters of the test specimens included axial-load eccentricity, tie spacing, and the use of concrete encasement. In addition to conventional perimeter ties, U-cross ties were used to prevent the premature spalling of thin concrete encasement as well as local buckling of longitudinal rebars. Although early vertical cracking occurred at the compressive face, the outer concrete significantly contributed to the stiffness and strength of the composite column without the premature failure. The test strengths were compared with the predictions of current design codes, addressing contributions of the whole encasement. The CEFT specimens showed substantial ductility even after the concrete crushing, owing to the increased resistance of the high-strength circular steel tube and confined infill concrete. To verify overall behavior of the test specimens, nonlinear numerical analysis using a fiber model was performed.

ABSTRACT: Local buckling may occur in the straight portion of a corrugated steel plate (CSP) pipe-arch with a deep wave section that is used in a buried structure. In this study, the soil support of the pipe-arch structure is considered, and the local buckling of the straight portion of the CSP is investigated. The corresponding theoretical formulae are derived using the Rayleigh-Ritz method. The simplified mechanical model with the soil support is used for derivation. Then, the finite element models for the invert of the pipe-arch with several waves are established to analyze the actual rotational restraints of the straight portion. The influences of plate thickness, corrugation, aspect ratio and curvature on the local buckling load of the invert are investigated. The relationships of plate thickness and local buckling load for three types of deep corrugations are obtained. These relationships reveal that the actual rotational restraints are negative, i.e., the straight portion provides restraint for the corrugated portion. Based on numerical simulations, the theoretical formulae are modified to account for the actual rotational restraints of the straight portion. Then, the finite element model of the global pipe-arch structure is built. The corresponding analysis matches well with the revised formula, which validates the modified derivation. Finally, according to the yield criterion, a reasonable limit value for the width-to-thickness
ratio for the straight portion of the CSP is suggested. This limit can be used to prevent local buckling of CSP buried pipe-arch structures in practice.

ABSTRACT: This paper presents and discusses numerical results on the (i) elastic post-buckling behaviour and (ii) imperfection sensitivity of simply supported cylindrical steel panels under uniform compression. The results presented are obtained by means of a geometrically non-linear Generalised Beam Theory (GBT) formulation previously reported by the authors, which can include arbitrary member initial geometrical imperfections. The modal decomposition features of GBT enables extending the knowledge on the mechanics underlying these structural elements, which cannot be obtained with standard shell finite element analysis. The work begins by describing the GBT buckling analysis of four curved panels with distinct curvatures. Then, post-buckling results are presented and discussed for each of the four panels geometries, by considering (i) two distinct critical-mode initial geometrical imperfections shapes and (ii) five distinct amplitudes to assess the imperfection sensitivity – if the “sign” of the initial geometrical imperfection is relevant, ten amplitudes are considered. These results provide the evolution, along the equilibrium paths, of relevant modal displacement profiles, modal participation diagrams and deformed configurations. For comparison and validation purposes, shell finite element results are also reported.

ABSTRACT: In this research, an analytical Jacobi-Ritz method for the free vibration analysis of composite laminated rectangular plate subject to arbitrary boundary conditions is proposed. The theoretical model is constructed in the framework of the first-order shear deformation theory (FSDT), and the multi-segment partitioning strategy is introduced. The boundary condition as well as the interface continuity condition is dealt with through the artificial spring technique. The displacement functions for every separated plate segment are expanded in the way of Jacobi polynomials along both the length and width orientations. And all the undetermined coefficients are decided through the Ritz method. The solution exhibits excellent convergence performance and shows stable features. The reliability and precision of the proposed methodology are validated by comparison with results from literature, where general boundary conditions are taken into account. Furthermore, parameterized study of the composite laminated rectangular plate is conducted, the results of which can be benchmark results for the future study.

ABSTRACT: This paper reports a numerical study on the local web buckling strength and behaviour of single-coped beam with slender web (SCBSW). First, finite element (FE) models of SCBSW connections were developed, and the effectiveness of the modelling techniques was validated by the results of full-scale SCBSW connection tests conducted by the authors and those in the literature. Subsequently, an extensive parametric investigation covering a wide range of web slenderness ratio, cope geometries and rotational stiffness of the
connection was conducted. A database of the FE results of 243 SCBSW models connected with a rotationally rigid support was developed. The analysis results show that all of the models were governed by local web buckling, and post-buckling behaviour of the SCBSW connections was confirmed. The interaction among the slender web, cope configurations and rotational stiffness of the connections on the structural behaviour and local web buckling capacity of SCBSW connections was characterised. A practical approach for evaluating the local web buckling strength of end-plate type SCBSW connecting with a rotationally rigid support was developed using the available FE results. The post-buckling behaviour and the interactive effect among the slender web and the other essential factors were considered in the proposed method. The proposed method produces reasonable predictions of the local web buckling strength of SCBSW connections with a rotationally rigid support comparing with those predicted by the FE results and the available test data, which may offer a basis for a full-fledged design guide for SCBSW.

ABSTRACT: As the highest and largest building in the nuclear power plant, the large-scale cooling tower is more likely to suffer the accidental or deliberate impact of the commercial aircraft, while few related studies have been conducted. By adopting the missile-target interaction method, the dynamic responses of the large-scale cooling tower under the impact of typical medium and large commercial aircrafts, i.e., Airbus A320 and A380, are numerically evaluated. Firstly, the refine finite element (FE) models of Chinese Chaohu hyperbolic cooling tower as well as the above two aircrafts are established by using the HyperMesh program. Then, by comparing with the classic Meppen-II-4 impact test (the fourth shot of the second series of Meppen impact tests) of large deformable missile and the modified Riera force function, the validations of concrete and aircraft models are verified respectively. Furthermore, the explicit dynamic analysis program LS-DYNA is used to perform the numerical simulations of the cooling tower collided by the two typical aircrafts. The whole impact processes are reproduced, and the impact force, damage and failure of the shell concrete, velocity of the aircraft are examined and discussed. Finally, the parametric influences of the impact velocity, angle, and position of two aircrafts on the damage and failure of cooling tower are further performed.

Zhixiang Li, Wen Ma, Ping Xu and Shuguang Yao (Key Laboratory of Traffic Safety on Track, Ministry of Education, School of Traffic & Transportation Engineering, Central South University, Changsha, China), “Crushing behavior of circumferentially corrugated square tube with different cross inner ribs”, Article 106370, Thin-Walled Structures, Vol. 144, November 2019, https://doi.org/10.1016/j.tws.2019.106370

ABSTRACT: In this paper, new designed circumferentially corrugated square tubes (CCSTs) with cosine and triangular corrugation cross-sectional profiles, respectively, are proposed for energy absorption. Three types of cross inner ribs, namely, crisscross, X shape and star shape, are introduced to induce the deformation of CCSTs. Quasi-static crushing test and finite element simulation were used to investigate the crushing performance of the CCSTs. The results showed that all triangular profile CCSTs can not deform stably, and only the crisscross inner rib can induce the deformation of CCSTs to deform progressively. The performance of cosine profile CCSTs with crisscross inner rib (i.e., CTC_C) under different geometric parameters was therefore further studied. It was found that the CTC_C develops four different deformation modes, and the ordered progressive mode II (OPM II) showed better energy absorption efficiency than the other modes. Finally, a theoretical model based on Simplified Super Folding Element method was presented to predict the mean crushing force of CTC_C deforming with OPM II. By comparing with the experimental and FE results, the theoretical model was proved to be very accurate.

ABSTRACT: Thin-walled structures are universally used as energy-absorption devices for their great crashworthiness characteristics and light weight. In this paper, a novel tubular configuration is introduced with a gradually decreasing amplitude of the corrugation profile in the axial direction, namely, a hybrid corrugated tube (HCT), to improve the energy-absorption capacities of ordinary corrugated tubes (OCTs). Based on the validated finite element (FE) models, the effects of geometric parameters of the HCTs on crashworthiness are investigated. The numerical results show the HCTs exhibit advantages on the energy absorption capability compared to OCTs, and the crashworthiness indicators and deformation modes of the HCTs depend strongly on the wavelength and constant corrugation ratio. The strengths of the HCTs gradually increases as the compression progresses, and when the constant corrugation ratio increases, the strengthening effect gradually weakens. By comparing OCTs and HCTs with the same wavelengths and deformation modes, it can be found that in the HCTs, the $SEA$ values increase by 21%–57%, the $F_m$ values increase by 15%–45%. The lower is the constant corrugation ratio, the more obvious are the increase in the $EA$, $SEA$, $F_m$ values. Finally, a multi-objective optimization is conducted to obtain the optimized HCT configuration for maximizing the $SEA$ and minimizing the $F_m$. The optimal HCTs are of even more superior crashworthiness and great potential as an energy absorber.

ABSTRACT: Aluminium honeycomb sandwich panels are an interesting lightweight structural solution for several applications such as marine structures, aerospace, automotive and aeronautics. In many of these applications, in-service conditions produce fatigue loadings: as a result, safer use of aluminium honeycomb sandwich structures requires a deep knowledge of their fatigue response, which was seldom studied in previous literature. The aim of the current study is to evaluate the fatigue response of aluminium honeycomb sandwich panels subjected to three-point bending loading conditions. The experimental investigation was performed on a commercial aluminium honeycomb sandwich structure with an overall thickness of 11 mm. A preliminary static analysis was performed both under three and four point bending conditions. The static tests allowed the identification of the static bending strength and the absence of a significant strain rate influence. Crashworthiness parameters were evaluated and a slight better performance was found under four point bending. The combination of static tests with Computed Tomography analysis resulted in the observation of the phenomena involved in static bending response of aluminium honeycomb sandwich structures, which are mainly dependent on cell walls buckling. Fatigue tests were conducted under three-point bending conditions. The influence of boundary conditions on fatigue life and on collapse modes were investigated by considering different supports spans. For one condition the $S$-$N$ curve was obtained and its equation was compared to literature results. Two different collapse mechanisms were observed depending on the supports span: for larger supports span a fracture of the tensioned skin was observed, whereas lower supports span produced core shear. The former mode differred significantly from static failure with the same boundary conditions. In both cases, failure occurred suddenly and this should be taken into consideration in industrial applications. An analytical model was applied to predict fatigue collapse modes and limit loads. A fatigue failure map describing the relationship between supports span, collapse modes and fatigue limit loads was obtained, in order to provide a quantitative tool for aluminium honeycomb sandwich structures design. The fatigue failure map was able to accurately predict the experimental results.

ABSTRACT: Honeycomb structures have been extensively employed as energy absorption devices. This paper proposes a kind of energy absorption structure known as the pre-folded honeycomb, which is made from conventional honeycomb with a pre-folded trace. The folding mode and energy absorption performance of the pre-folded structure under in-plane impact load were investigated both numerically and experimentally. Furthermore, the response surface method was chosen to find the optimal pre-folded honeycomb structure for the purpose of maximizing the specific energy absorption. The results demonstrate that the proposed method is effective in solving crashworthiness design-optimization problems. Additionally, the numerical results show that the in-plane structural strength of pre-folded honeycomb is nearly 8 times higher than that of conventional honeycomb.

ABSTRACT: To the best of our knowledge, this is the first trial to study the active vibration control of functionally graded multilayer graphene nanoplatelets (GPLs) reinforced composite plates integrated with piezoelectric layers. The theoretical formulation of the composite plates with piezoelectric layers is developed utilizing the element-free improved moving least-squares Ritz (IMLS-Ritz) method in association with the higher-order shear deformation theory (HSDT). Four GPLs distributions across the thickness of the GPLs reinforced composite layer are considered. For all distributions, the effective Young's modulus is calculated by the modified Halpin-Tsai model while the effective Poisson's ratio and mass density are estimated by the rule of mixture. Natural frequency results for GPLs reinforced composite plates with piezoelectric layers are presented considering various essential parameters including GPLs volume fractions, GPLs distribution patterns, plate's total thickness to width ratio, piezoelectric layer thickness to total plate's thickness ratio as well as boundary conditions. Additionally, the effects of these parameters on natural frequency increment between open and closed-circuit conditions are discussed. For active vibration control results, a constant velocity feedback controller is used considering two positions of piezoelectric sensor and actuator layers: the sensor and actuator layers are placed at two opposite sides or they are placed at the same side of the plates.

ABSTRACT: This paper presents an experimental and numerical study on the impact performance of circular concrete-filled double skin steel tubular (CFDST) members with external stainless steel tube. Austenitic 304 stainless steel was used for all the test specimens. Taguchi approach was employed for the parametric design of the experimental program. The testing parameters were the impact height, hollowness ratio and axial load level. 18 specimens were tested under transverse impact loading to obtain the failure patterns, the time histories of impact force and mid-span deflection, as well as the strain developments in the stainless steel tube. Finite element (FE) models were then established and verified against the test results, in which the strain rate effects of the stainless steel, the carbon steel and the infilled concrete were considered. The validated FE model was then employed to investigate the whole dynamic response of CFDST members with outer stainless steel tube subjected to impact. The impact resistance of the stainless composite member was also compared with that of the CFDST member with an external carbon steel tube.
Jianbin Cao, Zhusuo Zhang and Yanfei Guo (State Key Laboratory for Manufacturing and Systems Engineering, School of Mechanical Engineering, Xi'an Jiaotong University, Xi'an, 710049, P.R. China), “A finite element based state-space approach for vibration analysis of slender explosive clad pipe with partial contact defect”, Article 106359, Thin-Walled Structures, Vol. 145, December 2019, https://doi.org/10.1016/j.tws.2019.106359

ABSTRACT: An efficient modeling method is presented in this paper for vibration analysis of explosive clad pipe with partial contact defect (PCD). The principal purpose is to study the effects of the PCD on the vibration characteristics of explosive clad pipe and to explore effective techniques for detecting the PCD. The slender explosive clad pipe is regarded as two parallel elastic beams continuously joined by a virtual Winkler/Pasternak type viscoelastic layer, and the virtual layer is capable to describe the non-uniform bonding state such as the PCD. By means of finite element method and the standard linear solid (SLS) model, a state-space model of explosive clad pipe with inhomogeneous bonding state is developed for the fields of axial displacement and transverse displacement. The model can reflect the PCD pipe system under different boundary conditions and describe damping behavior of bonding interface. Experiments and numerical examples available in the literature demonstrate the accuracy and reliability of proposed approach. Finally, numerical results are presented and show that the PCD have significant effect on the natural frequencies and forced response in high-frequency domain. A potential method for identifying the length and position of the PCD in explosive clad pipe is also discussed in this paper.

ABSTRACT: Thin-walled conical shells are used as adapters between cylindrical shells of different diameters in launch-vehicle systems or as tailbooms in helicopters. A major loading scenario for conical shells is pure bending. The buckling moment of these shells is very sensitive to imperfections (geometry, loading conditions) which results in a critical disagreement between theoretical and experimental results for conical shells under pure bending. The design of these stability critical shells is based on classical buckling loads obtained by a linear analysis which are corrected by a single knockdown factor (0.41 - NASA SP-8019) for all cone geometries. This practice is well established among designers and hasn't changed for the past 50 years because the buckling behavior is till today not very well understood. Within this paper a reduced stiffness analysis for conical shells under pure bending is performed. Data of previous experimental testing campaigns are used to validate the new design criteria for different conical shell geometry configurations. The results show that the application of the new design recommendation for conical shell structures results in increased knockdown factors for the buckling moment which in turn may lead to a significant weight reduction potential. All ABAQUS-Python scripts and the results generated for this article are deposited in the Elsevier repository.

Zhichao Li, Subhash Rakheja and Wen-Bin Shangguan (School of Mechanical and Automotive Engineering, South China University of Technology, Guangzhou, 510641, China), “Study on crushing behaviors of foam-filled thin-walled square tubes with different types and number of initiators under multiple angle loads”, Article 106376, Thin-Walled Structures, Vol. 145, December 2019, https://doi.org/10.1016/j.tws.2019.106376

ABSTRACT: A finite element model of a thin-walled foam-filled square tube is developed for estimating its energy absorption characteristics. The crush behavior of the foam-filled tube is experimentally evaluated under axial loading and the measured force-deflection properties are used to examine validity of the model. The validated model is subsequently applied to study the effects of types and number of crush initiators on the energy absorption characteristics of the foam-filled thin-walled square tubes subjected to loading at different angles. It is shown that initiators can yield improved collision performance of the foam-filled thin-walled square
tubes, when a reasonable number of crushing initiators are introduced. The energy absorption performances of the foam-filled structure with different types and quantities of crushing initiators are calculated and ranked. The results showed best performance when a set of four-corner-holes along the axial direction of the tubes is added. Based on the model results, a multi-objective optimization method is proposed for deriving an optimal design of the tube with a set of four-corner-holes for enhanced crashworthiness performance.

ABSTRACT: This study investigates numerically and experimentally the effect of longitudinal ribbon reinforcement in conventional honeycomb structure on the various dynamic characteristics of a hybrid composite sandwich plate. Longitudinal strips are considered to be embedded along the transverse directions at various locations of a honeycomb core material without and with carbon nanotubes (CNT) reinforcement in a composite sandwich plate. The governing differential equations of motion of the various hybrid honeycomb composite sandwich plate configurations with strips inserted in conventional honeycomb structures as core layer having top and bottom face composite layers are derived using higher order shear deformation theory (HSDT) and solved numerically using a four noded rectangular finite element. Further, experimental investigations are performed by fabricating the various strips embedded hybrid honeycomb core material with and without CNT reinforcement to evaluate the shear and loss moduli using the alternative dynamic approach. The efficacy of the developed finite element formulation is demonstrated by comparing the experimental and numerical results obtained in terms of natural frequencies and loss factors for the various prototypes of honeycomb composite sandwich plates. Also, the effect of variation in CNT content and thickness of longitudinal ribbon reinforcement in conventional honeycomb core material and ply orientation of the face sheets on the various dynamic properties of hybrid composite structures are studied under various end conditions. This study proposes that the ribbon reinforcement location and the addition of CNTs in honeycomb core materials strongly influence the stiffness, damping and transverse vibration displacements of the ribbon reinforced hybrid composite sandwich plates.

ABSTRACT: Subsea pipelines and PIP systems experience large bending moments during installation and operation. However, unlike single-walled pipelines, the behaviour of PIPs under bending has been only marginally addressed. In the current study, the bending response of PIP systems with diameter-to-thickness ratio \((D/t)\) of 15–40 is investigated. Linear bifurcation analyses (LBA) and geometrically nonlinear analyses (GNA) are conducted on PIPs of varying lengths. Analytical expressions are provided to predict the classical and nonlinear limit moments of PIPs, and are compared to existing expressions for single-walled pipelines. Ultimate bending moments of PIPs are obtained from physical four-point bending tests and are compared against geometrically and materially nonlinear analyses (GMNA). The finite element results show that in PIPs with centralizers, the limit moments (GNA) drop slightly, however, the ultimate moments (GMNA) remain unchanged. A parametric study of the effect of geometry and material properties of the inner and outer pipes on the ultimate moment of PIPs is presented. It is understood that the ultimate moments of PIPs with thick tubes are predominantly influenced by the material nonlinearities rather than ovalization of the tubes.

Jagath Narayana Kamineni and Ramesh Gupta Burela (Multi-Functional Composites Lab, Mechanical Engineering Department, Shiv Nadar University, Greater Noida, UP, 201314, India), “Constraint method for

ABSTRACT: In this work, a new methodology is developed for constructing the stiffened panel structure. Here we introduce the constraint method to integrate the stiffener and plate. The geometric nonlinear analysis is performed to analyze the stiffened panel behavior in terms of load-deformation response curve. Variational Asymptotic Method (VAM) is applied to analyze composite flat stiffened panels. The VAM development begins with the 3-D nonlinear strain energy functional which splits into a 1-D through-the-thickness analysis and a 2-D plate analysis. The 2-D constitutive law that is an output of 1-D analysis is used as an input to perform the 2-D nonlinear plate analysis. The integration of skin and the stiffener technique is implemented by introducing a constraint matrix. At the skin and stiffener interface, the developed constraint matrix is used in realization of 3-D displacements of stiffener and skin are same. The proposed approach is simple and reliable to address the complexity in analyzing stiffened structures. This methodology is developed using a computational symbolic tool Mathematica and the implemented computer program named as NASSVAM (Nonlinear Analysis of Stiffened Structures using Variational Asymptotic Method). The obtained results from NASSVAM are compared and showed good agreement with the 3-D FEA results.

S. Mohsenizadeh and Z. Ahmad (School of Mechanical Engineering, Faculty of Engineering, Universiti Teknologi Malaysia, 81310, Johor Bahru, Malaysia), “Auxeticity effect on crushing characteristics of auxetic foam-filled square tubes under axial loading”, Article 106379, Thin-Walled Structures, Vol. 145, December 2019, https://doi.org/10.1016/j.tws.2019.106379

ABSTRACT: This paper treats energy absorption and crushing characteristics of auxetic foam-filled square-section tubes under axial loading condition. The influence of auxeticity effect on the structural collapse was experimentally investigated to quantify the interaction effect between Poisson's ratios of foam (ranging from −0.31 – 0.03) and square tube walls under quasi-static and dynamic loadings. The validated computer simulation technique was employed to conduct a series of parametric study in order to evaluate the influence of tube parameters on the energy absorption responses. It is evident that negative Poisson ratio effectively influences the crushing response and energy absorption capability of auxetic foam-filled square tubes. Moreover, it was found that increasing the auxeticity level of foam filler enhances crashworthiness performance of foam-filled structures under both quasi-static and dynamic loading conditions. The primary outcome of this study is a design guideline for the use of auxetic foam in different ranges of Poisson's ratio as a core for an energy absorber device where impact loading is expected.

ABSTRACT: Concrete-filled composite plate shear walls (CPSW) consist of a concrete (infill) wall sandwiched between two steel plates that are connected to each other using ties and anchored to the concrete infill using these embedded ties or shear connectors. Steel modules consisting of plates, ties and shear connectors are prefabricated in the shop, transported to the field, and assembled first. The erected modules serve as falsework for construction activities and stay-in-place formwork for concrete casting. This is a primary advantage and appeal of this system. However, there is a lack of knowledge regarding the structural behavior of empty steel modules (before and during concrete casting). This paper presents the results of analytical, numerical, and experimental investigations conducted to evaluate: (i) the structural behavior of empty steel modules under their own self-weight, (ii) the stability and axial load capacity of steel modules for construction loads and activities, and (iii) the effects of concrete casting (hydrostatic pressure) in terms of the deflections and stresses induced in the steel plates. The results indicate that the effective shear stiffness of the empty modules governs their structural behavior as well as their stability. The effective shear stiffness can be estimated using the finite element method (verified using test results), or conservatively using mechanics-based equations presented in this paper. The effective shear stiffness is governed by plate slenderness, defined by the tie spacing and plate thickness, and the relative flexural rigidity of the steel plates and the connecting ties. These parameters can be designed to limit the flexibility and the critical buckling stress of the empty modules. The paper also provides
equations for calculating the out-of-plane displacement and stresses induced in the steel plates by the concrete casting hydostatic pressure.

Habib Ahmadi and Kamran Foroutan (Faculty of Mechanical Engineering, Shahrood University of Technology, Shahrood, Iran), "Nonlinear vibration of stiffened multilayer FG cylindrical shells with spiral stiffeners rested on damping and elastic foundation in thermal environment", Article 106388, Thin-Walled Structures, Vol. 145, December 2019, https://doi.org/10.1016/j.tws.2019.106388

**ABSTRACT:** This paper presents the nonlinear vibration of multilayer FG cylindrical shells reinforced by spiral FG stiffeners surrounded by damping and elastic foundation in thermal environment. The primary, superharmonic and subharmonic resonances of spiral stiffened multilayer FG cylindrical shell are analyzed. It is assumed that the material properties are dependent to temperature. The linear elastic foundation is based on the Winkler and Pasternak model. In order to model the stiffeners, the technique of smeared stiffener is utilized. With regard to classical plate theory of shells, von Kármán equation and Hook law, the relations of stress-strain is derived for shell and stiffeners. According to the Galerkin method, the discretized motion equation is obtained. The primary, superharmonic and subharmonic resonances in presence of thermal environment are analyzed by using the method of multiple scales. The influence of the material parameters, temperature, elastic foundation and various geometrical characteristics on the primary, superharmonic and subharmonic resonances is investigated.

**ABSTRACT:** The lateral-torsional buckling of steel beams with welded slender I-shaped sections, or Class 4 sections according to Eurocode 3 classification, is investigated in this paper. While the response of non-Class 4 section beams has been extensively studied in the literature, welded slender section beams have received less attention to date.

Finite element (FE) models for non-linear analyses were developed and validated against 64 experimental tests available in the literature considering both material and geometrical imperfections. Subsequently, an extensive parametric study covering a wide range of sections and member geometries was carried out.

The existing rules from Eurocode 3 and a proposal based on a consistent derivation of the Ayrton-Perry formulation, developed for compact and semi-compact sections (sections of Class 1, 2 and 3), were presented and their accuracy was then evaluated using the numerical data generated.

As demonstrated, due to high width-to-thickness ratio of section's constituent plates, the coupled interaction between the local buckling and the lateral-torsional buckling affects the stability of the beams, but the design provisions deliver insufficient account of said interaction thus resulting in highly scattered predictions when compared against the numerical results, mostly yielding lower values of resistance than that obtained numerically.

To improve this condition, a novel concept, named the effective section factor (E.S.F.), was further developed to account with the coupled interaction by grouping the behaviour of beams with Class 4 sections into different ranges of E.S.F.

Finally, enhanced design formulae for the estimation of the ultimate strength of the beams was proposed based on the developed E.S.F. concept, providing more accurate capacity prediction.

**ABSTRACT:** In this paper the elastic buckling of longitudinally stiffened plates are discussed in the light of modal deformations. Though in the analysis and design of cold-formed steel members it is a widely used approach to decompose the deformations into global, distortional, local and other deformation modes, this approach has not been used for stiffened plates yet. In this paper a large number of stiffened plates are analysed with varying the plate width and thickness, the type, size and number of stiffeners. The investigated plates are subjected to uniform or linearly varying uniaxial compression as well as shear loading. Linear buckling analyses
are performed by enforcing various combinations of constraints, by using the constrained finite element method (cFEM). Regular unconstrained analyses are also completed, and the buckled shapes are identified with the help of cFEM, by calculating the participations from the characteristic deformation types. The results and tendencies are systematically and comprehensively evaluated. The completed studies reveal that though the geometric parameters and the load type have effect on the results, in the buckling modes with significant stiffener displacements the role of distortional and global modes is always crucial. This finding might have implication on the design, too. This question is discussed in detail in a companion paper, in which the Eurocode-based design of uniformly compressed stiffened plates with closed stiffeners are investigated.

ABSTRACT: Buckling resistance of longitudinally stiffened orthotropic plates is highly important in the design of steel bridges. The current calculation method of Part 1.5 of Eurocode 3 is based on the concept that the behaviour can be superposed from plate-like and column-like behaviours. Recent results indicate uncertainties in the application of the current method, e.g., if applied to plates with closed stiffeners. It is also known that the critical buckling stress is dependent on how it is calculated: by using a shell finite element model or by using the equations from Annex A of the relevant code part. The two calculation methods can lead to significant differences in the critical stress, which then mirrored in the resistance. Some results indicate that shell finite element calculation of the critical stresses can lead to resistance overestimation, especially when closed stiffeners are used. However, the reasons of the differences between the numerically and analytically calculated critical stresses are not yet fully clarified. Therefore, in the current paper the elastic critical buckling stress and buckling resistance of longitudinally stiffened plates are discussed. The paper presents the results of an extensive numerical research program focusing first on the critical buckling stress, then on the buckling resistance of plates with closed stiffeners. Reasons of the experienced differences between the critical stresses are explained in full detail. Moreover, possible enhancement of the resistance prediction is indicated.

ABSTRACT: Slender rectangular thin-walled concrete-filled steel tubular (CFST) columns in composite building structures exposed to fire may experience the interaction of local and global buckling. Numerical investigations on the interaction buckling responses of such columns under fire exposure have been rarely reported. This paper describes a fiber-based computational model for the prediction of the fire-resistance and interaction responses of local and global buckling of concentrically-loaded slender CFST columns made of rectangular sections exposed to fire. The thermal analysis is undertaken to calculate the distribution of temperatures in the column cross-section considering the effects of the air gap between concrete and steel, exposure surface emissivity as well as moisture content in concrete. The local and post-local buckling models proposed previously for steel tube walls at elevated temperatures are incorporated in the inelastic analysis of cross-sections to model the progressive post-local buckling. The global buckling analysis of slender CFST columns exposed to fire accounts for the effects of material and geometric nonlinearities as well as local buckling. Efficient computational procedure and solution algorithms are developed to solve the nonlinear equilibrium dynamic functions of loaded slender CFST columns exposed to fire. Independent experimental and numerical results on slender CFST columns are utilized to validate the computational model. The interaction behavior of local and global buckling and fire-resistance of slender rectangular CFST columns are investigated. It is shown that the developed computational model provides a reasonably accurate and efficient method for the
prediction of the interaction buckling responses as well as the fire-resistance of slender CFST columns subjected to axial loading and fire.

ABSTRACT: The effect of pre-stress on the buckling behaviour of geometric unit cells of collinear square lattices is investigated experimentally and numerically. The geometric unit cells are manufactured using fused deposition modelling. Manufacturing strategies are presented which incorporate fibres subjected to pre-stress within the unit cell. The effect of pre-stressed fibres is analysed by comparing the compressive behaviour of unit cells with and without fibre reinforcement. The buckling behaviour of the unit cells is also investigated numerically by employing a parametric study within Abaqus varying the pre-stress in the fibres. The experimental test series shows that the addition of pre-stressed fibres to the system results in an increase in buckling and maximum load of 260%–480% and 220%–350% respectively. The increase strongly relates to the manufacturing quality, i.e. the bonding between the lattice material and the fibres, where a sufficient bonding yields significantly larger loads. The experimental findings on the qualitative and quantitative buckling behaviour correspond well with results obtain from the numerical study.

ABSTRACT: The hot-press molding technique was developed to fabricate the Y-frame sandwich core from carbon fiber reinforced polymer composite. The three-point bending tests were conducted to investigate mechanical behavior of the Y-frame sandwich core. The effects of the relative density on the mechanical behavior of the Y-frame sandwich core were revealed by the experiments. The bending load-displacement curves were recorded, which indicated that the bending properties of the Y-frame sandwich core were strongly influenced by the relative density. The bending failure load and the value of P/delta were analytically predicted. The discrepancy between the experimental results and the predictions was analyzed. Furthermore, the analytical prediction also revealed that the value of P/delta was dependent on the span length of the composite Y-frame sandwich core.

ABSTRACT: This paper develops a high-performance semi-analytical numerical model to analyze the bending responses of the angle-ply composite laminated cylindrical shells with the fiber reinforced layers using the scaled boundary finite element method (SBFEM). As the thin-walled structures, the angle-ply composite laminated shells are assumed to be made of orthotropic materials in the cylindrical coordinate system. Both the geometric and basic variables are discretized by utilizing the two-dimensional (2D) high order spectral elements in the curved surface domain of the shells. According to the exact three-dimensional (3D) theory of elasticity rather than the approximate shell theories, the weak form of the partial differential governing equations for each layer of the composite laminated cylindrical shells in the cylindrical coordinate system are transformed into ordinary differential equations using the SBFEM. In the circumstances, there are no variables about the curved
surface of shell in the SBFEM governing equations for each lamina, so that it can be analytically solved on the basis of the dual variable approach and the precise integration technique (PIT). Employing the interface continuity conditions of displacement between the layers, the complete SBFEM model with respect to the global stiffness matrix of the composite laminated cylindrical shell can be obtained. Unlike the general layerwise theories, which supposes that the basic variables varied linearly with the thickness coordinate, the through-thickness distributions of the displacement field in each discrete layer is assumed to be a quadratic polynomial with respect to the radial coordinate in this paper, thus the through-thickness stress field can be described more accurate. Numerical examples for solving the bending problem of composite laminated cylindrical shells are presented. As a result, the numerical efficiency, accuracy and applicability of the proposed formulations are confirmed by the comparison of the published results involving the distributions of the displacements and stresses through the thickness and along the circumferential direction for different staking configurations, geometric properties and boundary conditions.

ABSTRACT: Sandwich structures were built up by two glass fibre reinforced polymer (GFRP) thin-walled panels and square hollow sections (SHS) in between through adhesive bonding or mechanical bolting. Experiments in compression were conducted in order to understand the failure modes including global and local buckling, load-bearing capacities, load-displacement curves and load-strain responses. Accordingly the effects of different connection methods and different spacing values between the SHS sections were clarified. Sudden debonding failure between GFRP panels and inner SHS columns was found on adhesively bonded specimens; while mechanically bolted specimens showed evident lateral deformation and progressive failure until the ultimate junction separation failure on the GFRP SHS columns. Local buckling was found on GFRP thin-walled panels of specimens with a larger spacing between the two SHS sections. Finite element analysis and analytical modelling were performed to estimate the load-displacement curves and the critical stress for the local buckling on GFRP thin-walled panels, where consistent agreements with experimental results were received.

ABSTRACT: Multi-cell design and graded thickness are two efficient strategies for improving the mechanical behaviors of metallic thin-walled tubes. This paper combines these two strategies to present a novel multi-cell structure with a double surface gradient (DSG) and to address the energy absorption characteristics of the new tube subjected to axial compression. A mathematical formulation for the mean load was derived through theoretical analysis of the multi-cell structure's folding mechanism, and two vital parameters were proposed. Afterwards, comprehensive numerical simulations were conducted to validate the formulation and to investigate effects of the DSG on the mechanical properties. The results demonstrated that the combination of the DSG strategy and the multi-cell structure led to a greater energy absorption capacity. Finally, the key factor of the DSG design in promoting the energy absorption efficiency was analyzed. To achieve a higher promotion, an approach of rationalizing the sectional material distribution of the DSG tube was attempted and proven valid. All these achievements shed a light on the multi-cell and graded thickness effects on mechanical properties.
ABSTRACT: This paper presents a numerical-experimental research to evaluate the effect of corrosion in panels subjected to uniaxial compression and subsequent repair. The effects of corrosion are approximated by a uniform reduction in the plating's thickness. Currently, repairing a corroded offshore structure involves the change of the hull plating, which is excessively expensive and, therefore, other alternatives should be investigated in order to extend its useful life. The experimental study considers a set of five panels with an average scale of 1:3.5, representing a typical intact panel of a VLCC (Very large Crude Oil Carrier) converted into a FPSO (Floating Production Storage and Offloading) platform and two different plating reduction thickness levels. These experiments are reproduced through a numerical model that considers geometric and material nonlinearities. The geometrical imperfections in the surfaces of plates and stiffeners are reconstructed from measurements using techniques of laser scanning and optical capture. Thickness distributions are measured with an ultrasonic sensor in several predetermined panel sections points. True stress vs true strain curves for all panel's elements are obtained by tensile tests and employed in the numerical model. Once the numerical model is validated, the effect of the axial load eccentricity, the supported element load redistribution due to changes in the thickness, and the effects of the inclusion of intermediate repair on the plate are studied. The results show that the inclusion of an intermediate light stiffener allows recovering the panel load capacity and prolonging the useful life of offshore platforms. Likewise, it is concluded that the selection of the repair should be based on the local strength recovery of the plate, which is most affected.

ABSTRACT: The repair of fire-damaged thin-walled rectangular concrete-filled steel tubular (CFST) columns in engineering structures after fire exposure requires the assessment of their residual strength and stiffness. Existing numerical models have not accounted for the effects of local buckling on the post-fire behavior of CFST columns with rectangular thin-walled sections. This paper describes a nonlinear post-fire simulation technique underlying the theory of fiber analysis for determining the residual strengths and post-fire responses of concentrically loaded short thin-walled rectangular CFST columns accounting for progressive local buckling. The post-fire stress-strain laws for concrete in rectangular CFST columns are proposed based on available test data and implemented in the theoretical model. An innovative numerical scheme for modeling the progressive local and post-local buckling of CFST thin-walled columns is discussed. The nonlinear post-fire simulation model is verified by experimental data and then used to investigate the significance of local buckling, material strengths and width-to-thickness ratio on the post-fire responses of CFST stub columns. The proposed post-fire computer model is shown to be capable of predicting well the residual stiffness and strength of concentrically loaded thin-walled CFST columns after fire exposure. A design formula is proposed that estimates well the post-fire residual strengths of CFST columns. Computational results presented provide a better understanding of the post-fire behavior of CFST columns fabricated by thin-walled sections incorporating local and post-local buckling.

ABSTRACT: This paper presents a numerical-experimental research to evaluate the effect of corrosion in panels subjected to uniaxial compression and subsequent repair. The effects of corrosion are approximated by a uniform reduction in the plating's thickness. Currently, repairing a corroded offshore structure involves the change of the hull plating, which is excessively expensive and, therefore, other alternatives should be investigated in order to extend its useful life. The experimental study considers a set of five panels with an average scale of 1:3.5, representing a typical intact panel of a VLCC (Very large Crude Oil Carrier) converted into a FPSO (Floating Production Storage and Offloading) platform and two different plating reduction thickness levels. These experiments are reproduced through a numerical model that considers geometric and material nonlinearities. The geometrical imperfections in the surfaces of plates and stiffeners are reconstructed from measurements using techniques of laser scanning and optical capture. Thickness distributions are measured with an ultrasonic sensor in several predetermined panel sections points. True stress vs true strain curves for all panel's elements are obtained by tensile tests and employed in the numerical model. Once the numerical model is validated, the effect of the axial load eccentricity, the supported element load redistribution due to changes in the thickness, and the effects of the inclusion of intermediate repair on the plate are studied. The results show that the inclusion of an intermediate light stiffener allows recovering the panel load capacity and prolonging the useful life of offshore platforms. Likewise, it is concluded that the selection of the repair should be based on the local strength recovery of the plate, which is most affected.

ABSTRACT: The objective of this paper is to develop a constrained shell Finite Element Method (cFEM) based on a force approach for elastic buckling analysis of thin-walled members. The new cFEM is able to separate the general deformation of thin-walled members into the three fundamental deformation mode classes, namely Global (G), Distortional (D), and Local (L), to enable the modal decomposition and identification. In this paper, four force-based mechanical criteria are defined to separate these mode classes. These mechanical criteria are implemented with the general shell finite element formulation without any special treatment of the element formulation. The constraint matrices of the G, D, and L mode classes are then constructed. Numerical examples are presented to demonstrate the capabilities of the new cFEM in modal decomposition and identification. In particular, the modal decomposition and identification results are compared with the cFSM solutions. Applicability of the new cFEM to other shell FE formulation and different loading conditions are illustrated. All these numerical examples demonstrate the potential of the developed cFEM in taking advantages of the modeling capability of the existing shell FE method.

ABSTRACT: The axial splitting of thin-walled tube is usually considered as an efficient deformation mode to dissipate impact energy thanks to its large stroke ratio. However, the low crushing force and the unstable deformation process, such as crack merging and branching, significantly limit its application in crushworthiness design. In this paper, we propose to enhance the deformation stability through introducing initial kerfs on the inner and outer surfaces of the circular steel tube in its axial direction to guide the propagation of cracks during the splitting process, thus we can improve the crushing force via a significant increase in tube wall thickness. To demonstrate the feasibility of the proposed method, quasi-static compressive experiments on single tube (inner radius \( r=55 \text{mm} \), wall thickness \( t=5 \text{mm} \)) and doubled tube (consisted of two tubes with wall thickness \( t=5 \text{mm} \)) with kerf depth \( \delta=0.5 \text{mm} \) split by a radiusied die are performed, which exhibit stable deformation processes and high steady-state compression forces (103.32 kN for single tube, and 216.44kN for doubled tube). Then, finite element simulations are conducted to model the tested samples. It is found that the experimentally observed deformation processes are well captured by simulations, and the relative errors of numerical steady-state compression forces in comparison to experimental results are 0.39% (single tube) and 1.90% (doubled tube), respectively. Finally, based on the validated numerical model, the influence of tube and die dimensions on its crushworthiness performance is discussed. It is observed that the axial load significantly depends on kerf depth, crack number, and tube thickness. The curling radius is nearly not affected by kerf depth, but it almost linearly depends on die radius. Moreover, the tube with larger wall thickness has a higher specific energy absorption.

ABSTRACT: This paper quantifies the influence of uncertainty in the low-velocity impact responses of sandwich plates with composite face sheets considering the effects of obliqueness in impact angle and twist in the plate geometry. The stochastic impact analysis is conducted by using finite element (FE) modelling based on an eight nodded isoparametric quadratic plate bending element coupled with multivariate adaptive regression spline (MARS) in order to achieve computational efficiency. The modified Hertzian contact law is employed to model contact force and other impact parameters. Newmark’s time integration scheme is used to solve the time-dependent equations. Comprehensive deterministic as well as probabilistic results are presented by considering the effects of location of impact, ply orientation angle, impactor velocity, impact angle, face-sheet material property, twist angle, plate thickness and mass of impactor. The relative importance of various input parameters
is determined by conducting a sensitivity analysis. The results presented in this paper reveal that the impact responses of sandwich plates are significantly affected by the effect of source-uncertainty that in turn establishes the importance of adopting an inclusive stochastic design approach for impact modelling in sandwich plates.

ABSTRACT: Thin-walled structures such as those used for space launch vehicles are prone to buckling when axial load is applied. These structures can be designed as imperfection-sensitive structures in the form of unstiffened shell structures or else as imperfection-tolerant structures by applying frames and stringers to the shell structure. Weight-Strength-Curves can be applied to compare structural concepts from a pure technological point of view, where neither costs of manufacturing nor the manufacturing signature are taken into account. Within this paper, a cost model for unstiffened isotropic shell structures based on the assembly output of multiple panels is introduced. Furthermore, a relation between the manufacturing process and the load carrying capacity of an isotropic shell structure is derived. On this basis a coupled structural and economical design procedure is evolved. In a final step, an example is introduced in order to illustrate the application of the coupled design procedure and to derive a structure which is optimized with regard to its structural mass and manufacturing costs. Based on this example it is shown that the chosen panel size affects not only the manufacturing costs, but also the load carrying capacity.

ABSTRACT: The objective of this paper is to computationally investigate the fire resistance of earthquake-damaged thin-walled tubular T-joints stiffened with internal rings at elevated temperatures. An earthquake can cause severe damage to the T-joints, thus may lead to the reduction of fire resistance after that. Additionally, given the needs in improving the performance of T-joints using stiffeners, the behaviors and fire performance of these stiffened T-joints under post-earthquake fire (PEF) is of great interests. A computational model, validated with the existing experimental results, is established to conduct the analysis of the fire resistance behavior of the stiffened tubular T-joints under PEF. Then, by using this model, the stiffening strategies for tubular T-joints using 1 internal ring, 2, and 3 internal rings, are evaluated along with the unstiffened case to investigate their effectiveness in improving the fire resistance capability under PEF. Later, a parametric study is performed for the stiffened T-joints with 3 internal rings under PEF using the validated computational model. 24 finite element models are analyzed under different damage levels, by considering the following key geometric parameters: the diameter ratio (β), the wall thickness ratio (γ) of the T-joint's chord and brace members, the diameter-thickness ratio (α) of the chord member, and the thickness ratio η of ring-stiffener and chord along with the damage variable (D̄) to account for the level of the T-joint being damaged. The results on different stiffening strategies and the parametric study reveal that the significant influence of the damage variable and the sensitivities of other influencing parameters. The findings from this study provide needed evidence for potential design recommendations for post-earthquake fire resistance of stiffened tubular T-joints.

ABSTRACT: In this paper, tubes with different axial corrugations were studied under axial loading. Accordingly, a new axially half-corrugated thin-walled tube was developed to improve the energy absorption characteristics. The forming process of the corrugations on the tubes has also been described. Comprehensive experimental and numerical analysis have been conducted in order to investigate the effects of various geometrical parameters on crushing behavior of the structure. It has been shown that by the use of the new axially half corrugated tube, there is much more efficient crushing via a more uniform force-displacement result as well as a considerable improvement in other crashworthiness characteristics. Subsequently, a numerical study has been conducted on the same tubes to both have the numerical results validated and assure the repeatability and reliability of the experimental results. An efficient model in axial loading has been obtained which is offering a perfect concertina form. The obtained model deforms through an inversion mode causing an extra frictional force between the inverted part and the tube itself, resulting in a considerable increase in SEA, mean force, and consequently CFE.

ABSTRACT: It is well-known that the buckling response of thin-walled structures is greatly affected by initial geometrical imperfections. In this study, the uncertainty in such geometrical imperfections is modelled by a non-probabilistic field model that is a reasonable and convenient alternative to the probabilistic random field representation of uncertainties with limited samples. After representing the bounded field uncertainty as a function of a reduced set of uncorrelated uncertain coefficients using the series expansion method, the buckling assessment problem of thin-walled plates is then constructed to minimize the critical buckling load under the non-probabilistic field description of imperfections and the volume constraint of plates. The optimization problem is solved effectively using a standard gradient-based algorithm with adjoint-variable sensitivity analysis. Numerical examples are given to demonstrate the validity and applicability of the proposed model for assessing both the critical buckling load and the worst imperfection pattern in thin-walled plates.

ABSTRACT: This paper investigates the buckling behaviors of thin rectangular functionally graded carbon nanotubes reinforced composite (FG-CNTRC) plate subjected to the arbitrarily distributed partial edge compression loads. Three distribution types of carbon nanotubes (CNTs) are considered and the effective material properties of carbon nanotube reinforced composite are given according to the extended rule of mixture, in which the distribution uncertainty of CNTs is also taken into account. Based on the differential quadrature method (DQM) and work equivalent method, the pre-buckling in-plane stress distribution of thin rectangular FG-CNTRC plate are determined firstly. Then the accurate critical buckling loads and buckling modes of FG-CNTRC plate are consequently obtained. By comparing with the results in published literatures, the feasibility and accuracy of present numerical method are validated. Finally, the systematic parametric studies are carried out to elaborate the effects of distribution type, volume fraction and distribution uncertainty of CNTs as well as the distribution width, position and distribution type of partial edge compression loads on the buckling behaviors of thin rectangular FG-CNTRC plate for the first time.

ABSTRACT: The mechanical property of anti-trichiral honeycombs under large deformation along the x-direction are studied by both experiments and theoretical analysis. It's shown that the elastic-plasticity bending occurs in the ligaments besides the plastic hinges, which is very different from the deformation mode under the y-directional compression reported previously. Based on the cells’ deformation mechanism observed in experiments, an analytical model is established to derive the Poisson's ratio and the crushing stress of the anti-trichiral honeycomb. The theoretical predictions are verified by the experimental results. It is shown that the crushing stress increases with the wall thickness t, but decreases with the ligament's length L. As for the Poisson's ratio, it increases with L, but decreases with the honeycomb's deformation, while the ligament's wall thickness t makes no difference to it. Moreover, it is revealed that the negative Poisson's ratio effect of the anti-trichiral honeycomb under the x-directional compression is stronger than that under the y-directional compression, while the superiority of the crushing stress along these two directions depends on the cell's geometry parameters.

ABSTRACT: In this paper, a numerical investigation is carried out for determining the influence of imperfections on the lateral-torsional buckling of welded I-shaped slender section beams. The buckling resistance of unrestrained beams is calculated with nonlinear shell-element based FE analysis, including material and geometrical imperfections. The sensitivity to global and plate imperfections, as well as residual stresses, is presented for different amplitudes and shapes of geometrical imperfections and distributions of residual stresses available in the literature. The recommendations outlined in this work shall help the choice of these parameters on future numerical simulations and extend the observations of other authors in the context of studies for beams with non-slender sections.

The comparison of the numerical results with the predictions of the North American design code, AISC360-16, and the European design code, Eurocode 3, suggests that the AISC360-16 provides an upper limit for the beam’s resistance and the Eurocode 3 a lower bound, mainly because residual stresses have a greater impact in the load-carrying capacity on the studied beams. Thus, these findings are expected to promote future developments and amendments to said design codes.

Finally, this investigation also supports the need of more realistic definition of imperfections, especially for the case of residual stresses, and justifies a more comprehensive experimental campaign on the subject.

ABSTRACT: In this article, a refined modified couple stress theory based on isogeometric analysis to capture the small-scale effect on laminated composite micro-plates is developed for the first time. Based on Hamilton's principle, the weak form for composite plate is established by using the Reddy's third order shear deformation theory without shear correction factor and the refined modified couple stress theory. Unlike the modified couple stress theory, which contains only one material length scale parameter, the proposed theory contains three
material length scale parameters. To confirm the accuracy of the proposed method, several examples are presented, discussed and compared to references' solutions. In addition, cut-out complicated shapes are analyzed to show the influences of the small-scale effect on free vibration behaviors of laminated micro-plates. An increase in the material length scale parameter leads to decrease in the deflection, stresses and increase in frequencies and critical buckling load factor. The presented numerical results show the great efficiency of the NURBS-based isogeometric analysis for capturing the small-scale effect of the composite laminated micro-plates.

ABSTRACT: A calculation of the elastic buckling load for cellular columns with multiple circular openings is required to determine their axial load capacity. Due to the complexity of column geometry and shear effects, the available methods to analyze the elastic buckling load are limited. This study proposes a method of calculation the elastic buckling load about the major axis of a pin-ended cellular column. The analysis is based on simplification of the column geometry and uses an effective length of shear force transfer across openings in the columns. The shear force in the column causes additional deformations of the web-post and the Tee section of cellular columns. The buckling load is derived by using differential equations of total curvature of the buckling curve, which is the sum of curvatures due to moment and shear forces. The proposed buckling load estimate is validated by comparisons with finite element analysis. A parametric study of the column geometry effects on shear, such as the section ratios, the opening ratios, the spacing ratios and the slendernesses, was also conducted. The shear effects clearly increases with open area fraction in the web, and with the section ratios. It was found that the spacing ratio affects the buckling load more than the opening ratio. Overall, the shear effects degrade the buckling load by less than 20% when the slenderness exceeds 50 compared to the Euler buckling load.

ABSTRACT: Thin-walled steel tubular circular columns are becoming an increasingly attractive choice as cantilever bridge piers due to their architectural, structural and constructional advantages. This paper aims to evaluate the strength and ductility of thin-walled steel tubular circular columns with uniform thickness (BC) and graded thickness (BGC) under bidirectional cyclic lateral loading in the presence of constant axial force. The analysis is carried out using a finite-element model (FEM) which is substantiated based on the experimental results in the literature. Then, the proposed BGC column with size and volume of material equivalent to the BC column is investigated. As a part of this research, a comprehensive parametric study is carried out to investigate the effects of main design parameters including: radius-to-thickness ratio parameter \( \alpha \), column slenderness ratio parameter \( \lambda \), magnitude of axial load \( (P/P) \), and number of loading cycles \( N \) on the strength and ductility of both BC and BGC columns under bidirectional cyclic lateral loading. Finally, design formulae of ultimate strength and ductility of BC and BGC columns are derived.

ABSTRACT: This paper addresses the thermal buckling behavior of tanks having a fixed roof, as employed to store fuel in the oil industry. The study is performed based on finite element analyses of the shell, including linear analysis, linear bifurcation analysis, and geometrically and constitutive nonlinear analysis, in order to elucidate the mechanics of stress redistribution at pre-buckling and buckling states. Based on previous works, the roof is modeled as a conical shell with an equivalent uniform thickness. The results show that the stress field due to a uniform temperature around the circumference is considerably different from that obtained for a non-uniform field as modeled in cases of temperatures due to an adjacent fire: Under uniform temperatures around the circumference the shell does not provide vertical restrain and buckling is dominated by hoop action; whereas displacement constraints are present under a non-uniform temperature, leading to buckling dominated by meridional stresses. Contrary to what has been suggested, the tank under uniform temperature cannot be taken as an upper bound to the buckling of a tank under an adjacent fire. In the evaluation of critical temperatures, the influence of geometric relations \(H/D\) (height to diameter) and \(R/t\) (radius to thickness) are independent of each other. It is shown that the problem is not imperfection-sensitive. Finally, thermal buckling mode and critical temperatures are strongly dependent on the \(H/D\) ratio of the cylindrical shell.

ABSTRACT: The vibration characteristics of sandwich panels with a hierarchical composite honeycomb sandwich core were investigated in this study. An orthotropic constitutive model of the hierarchical composite honeycomb sandwich core was used to propose an equivalent model (two-dimensional model). Two-dimensional (2D) and the three-dimensional (3D) finite element models as well as modal tests were used to predict the natural frequencies and mode shapes of the sandwich panels. The prediction results obtained using the equivalent model were consistent with the experimental and 3D finite element analysis results. Subsequently, a redesigned sandwich panel, with a hierarchical cross-honeycomb sandwich core, was manufactured to implement the multifunctional characteristics such as fluid flow and installation of microelectronic devices. To compare the vibration characteristics of the panel with a hierarchical cross-honeycomb sandwich core with those of a panel with a hierarchical square-honeycomb sandwich core, a dimensionless frequency parameter, \((\omega \text{-sub-1}/\omega)\), was proposed. The frequency parameter had different sensitivities to the geometric parameters, \(i.e.,\) the face-sheet thickness ratio, wall-sheet thickness ratio, and relative density of the filling foam.

Di Wang, Lei Wu, Yun Zhu, Xian Wang and Yueming Li (State Key Laboratory for Strength and Vibration of Mechanical Structures, Shaanxi Key Laboratory of Environment and Control for Flight Vehicle, School of Aerospace Engineering, Xi'an Jiaotong University, Xi'an, 710049, PR China), “Vibration of a plate coupled with fluid considering the effects of stress and deformation under hydrostatic load”, Article 106413, Thin-Walled Structures, Vol. 145, December 2019, https://doi.org/10.1016/j.tws.2019.106413

ABSTRACT: The effects of inner stress and geometric deformation caused by hydrostatic load on the vibration of a bottom plate-fluid coupled system are studied in detail. The Von Karman nonlinear strain displacement relationship and the Hamilton's principle are utilized to formulate the two sets of governing equations: nonlinear static equations under hydrostatic load and linear vibration equations of the plate-fluid coupled system considering the hydrostatic load effect at the nonlinear static position. A two-step theoretical approach is developed based on the equations. Experimental and numerical researches are carried out to validate the theoretical approach, and the natural frequencies derived by the three approaches coincide well. The results show that with the fluid height increasing, the natural frequencies of the plate decrease sharply at the very beginning, then increase constantly except that the fundamental frequency continues to decrease slowly. That means the added mass effect is the dominating effect when the fluid height is low, and the stiffening effect of the hydrostatic load plays a more important role with the fluid getting higher. The stress and deformation effects
are considered respectively and compared in detail. Models with different fluid-plate size ratios are studied. Moreover, the hydrostatic load effect on the hydroelastic vibration responses of the plate is also analyzed.

ABSTRACT: This paper reports the latest developments concerning the use of Generalised Beam Theory (GBT) in the field of steel-concrete composite beams. In particular, a GBT-based finite element is presented that uses a linear visco-elastic material law to capture, accurately and efficiently (with a very low computational cost), the effects of concrete creep, as well as cross-section distortion and shear lag in complex cross-sections (combining closed cells and open branches). It is shown that the versatility of the GBT approach makes it possible to obtain accurate solutions with a fairly small number of cross-section deformation modes (cross-section DOFs), leading to significant computational savings with respect to standard shell finite element models. Several numerical examples are presented, to illustrate the capabilities and potential of the proposed GBT-based finite element.

ABSTRACT: In this paper, the crushing behavior of hybrid metal-composite conical tube under dynamic loading is studied. An efficient analytical solution for FML conical tubes consist of any number of metal and laminated composite layers is developed. In the analytical analysis, the mean collapse load of structures subjected to axial loading was predicted while its accuracy is validated via experimental tests and numerical simulation. Numerical simulation of the structure is also done using explicit dynamic finite element software in order to investigate the effects of different parameters on crushing characteristics of various structures. On the other hand, new values for failure energies of fiber reinforced composites are proposed in the failure evolution criteria in the finite element model. It leads to good agreement between FE simulations and experimental test other. Moreover, a comprehensive parametric study has been done in order to investigate the effect of various parameters including semi-apical angle, ply pattern of laminated composite, diameter of tube, wall thickness and material properties of tubes on energy absorption capacity and crashworthiness characteristics of various considered specimens. Finally, the crashworthiness capacity (SEA and CLE) with respect to semi-apical angle and ply pattern of laminated composite optimized in order to obtain a desired collapse mode. Based on the obtained results the optimized structure is determined. Also, crushing behaviors of various specimens predicted beyond the tested configurations using response surface methodology (RSM).

ABSTRACT: The paper investigated the free vibration of combined spherical-cylindrical-spherical (CSCS) shell with non-uniform thickness based on Ritz method. The energy method and first-order shear deformation theory are adopted to derive the formulas. The displacement functions are improved on base of domain decomposition method, in which the unified Jacobi polynomials are introduced to represent the displacement functions component along axial direction. The displacement functions component along circumferential direction is still Fourier series. In addition, the spring stiffness method is formed to be a unified format to deal with general boundary conditions. Then the final solutions are obtained by using Ritz method. To prove the validity of this method, the results of the same condition are compared with those obtained by FEM, published
lithatures and experiment. In addition, some meaningful examples are provided to reveal the free vibration characteristics of stepped spherical-cylindrical-spherical shell. The results of this paper can be used as the reference data for future research in related field.

ABSTRACT: Rectangular Levy-type plates restrained using point-supports have wide engineering applications. However, the analytical solutions for the buckling behaviour of such plates are not well developed. This paper presents the derivation and application of analytical solutions for the buckling analysis of Levy-type rectangular plates with arbitrarily positioned single or multiple point-supports, which may be located on free edges or within the interior domain. Two general approaches, the impulse function approach (IFA) and the flexibility function approach (FFA), are developed to obtain the critical buckling coefficients ($K_c$) and buckled shapes of point-supported rectangular plates. In the IFA, the shear or moment distribution is expressed using a Fourier expansion of the impulse function whereas in the FFA a flexibility function, with zero values of the deflection at the point-support locations and sufficiently large values over the rest of the plate, representing the fictitious elastic distribution, is used to modify the plate support conditions. These approaches are employed in both one-dimensional (1D), and two-dimensional (2D) forms. The developed methods can be adopted to analyse any rectangular Levy-type plate subjected to uniaxial or biaxial loads restrained by arbitrarily positioned point-supports. The IFA and FFA results are validated with finite element method solutions obtained using Abaqus software. Several examples of buckling behaviours, including primary Levy-type plates, edge point-supported plates, as well as single and two interior point-supported plates are provided as guidelines for future design purpose.

ABSTRACT: The structural behavior of concrete-filled hot-finished (HF) and cold-formed (CF) steel elliptical tubular stub columns was investigated and is presented in this paper. A series of tests was conducted on HF and CF steel elliptical tubular sections infilled with three different concrete grades, namely C40, C80 and C100. The tested HF and CF steel elliptical hollow sections (EHS) had an aspect ratio of 2 with the same nominal section dimension of 200×100×6.5 mm. The test specimens were subjected to uniform axial compression. The initial local geometric imperfection measurements, ultimate loads and failure modes of the concrete-filled HF and CF EHS stub columns are presented. An extensive numerical study accounting for the confinement effect, as well as the non-linearities of materials, geometry and contacts was also performed. After a successful model validation against test results, a parametric investigation was conducted by considering a wide range of the cross-section dimensions and section slenderness of HF and CF EHS with different grades of the infilled concrete. A total of 111 concrete-filled HF and CF EHS specimens were carefully designed and analyzed by using the validated numerical model. The behavior of concrete-filled HF and CF EHS stub columns was investigated, including the maximum load, end shortening, strength enhancement index and ductility index. Effects of section strength factor and column sectional characteristics on the stub-column behavior were also investigated. Furthermore, the experimental and numerical results were used to assess the suitability of the design equations specified in the current American Specifications (AISC and ACI) and European Code (EC4) for the compressive resistance of the concrete-filled HF and CF EHS stub columns. It was found that the predictions from the current international design specifications were overall conservative for both concrete-filled HF and CF EHS stub columns. Generally, the predictions by EC4 were less conservative but more scattered than those predicted by AISC and ACI specifications for the concrete-filled HF and CF EHS stub columns.

ABSTRACT: Mass efficient thin-walled rectangular hollow section (RHS) struts have been shown to be susceptible to local–global mode interaction and exhibit sensitivity to imperfections. Material nonlinearity may increase the imperfection sensitivity of such members further and affect the final failure mode. Nonlinear finite element (FE) models for welded inelastic thin-walled RHS struts with pre-defined local and global geometric imperfections alongside residual stresses are developed within the commercial package Abaqus and validated against two independent experimental studies. Based on the validated FE model, the effects of material nonlinearity and residual stresses from welding on the ultimate load, mechanical behaviour and the imperfection sensitivity of struts are investigated. A simplified method to determine the initial geometric imperfection amplitude introduced in the FE model with residual stresses explicitly modelled within the ECCS framework is proposed for the first time. The experimental and numerical results in conjunction with existing experimental results from the literature are employed in the companion paper for the assessment of the Effective Width Method and Direct Strength Method, which also forms the basis for a new set of design recommendations.

ABSTRACT: The second part of the study on the local–global mode interaction in thin-walled inelastic rectangular hollow section struts focuses on design guidance. Based on the validated finite element (FE) model from the companion paper, a framework for fully automating FE model generation, submission and post-processing for geometric and material nonlinear analysis with imperfections is first presented. The ultimate load data for specimens with different cross-section aspect ratios, cross-sectional slenderness, global slenderness and welding options are generated. The current design rules for thin-walled welded RHS struts are assessed using the numerical results and existing experimental results from the literature by means of structural reliability analysis in accordance with the methodology presented in Annex D of Eurocode EN1990. A modified Direct Strength Method (DSM) relationship is then proposed and it is demonstrated to provide superior ultimate load predictions than the current guidelines.

ABSTRACT: An extensive numerical study of Class 4 section beams at elevated temperature is described in the paper. The study focuses on welded I-section beams of slender web and flange and covers beams of constant height as well as beams with significant web taper ratio. The numerical parametric study extends previous test results significantly in terms of various temperatures, section slenderness for flange and webs considering also combination of more stocky flanges with a slender web, various beam slenderness and moment distribution along the beam. Based on the numerically calculated resistances, a simple design rule was developed for both constant and web tapered members. The proposed model is believed to be predicting the beam capacity accurately with formulas simple enough to be used and accepted by structural engineers.

ABSTRACT: There is a lack of investigation on the nonlinear stability analysis of large steel hyperbolic cooling towers considering imperfection sensitivity. In this paper, nonlinear stability analysis of 150m-height steel hyperbolic cooling towers was assessed. Models with five structural systems were established, including two types of reticulated shells (i.e., single-layer and double-layer shells) and three forms of girders (i.e., triangular, rectangular grid, and square pyramid grid). Additionally, geometrically and material nonlinear stability analyses for more than 220 cases were conducted considering various distributions and amplitudes of imperfections. The results showed that the five hyperbolic steel cooling towers are of relatively low imperfection sensitivity, which is different from most other thin-walled shells, and the imperfection sensitivity of rectangular grid is high, while triangle grid and square pyramid grid are of low imperfection sensitivity. In addition, structures with double-layer reticulated shells are more sensitive to imperfection than those with single-layer ones. It is recommended that the design of steel cooling towers can give priority to the scheme of single-layer reticulated shell with triangular grid. Furthermore, the imperfection amplitude of H/300 could reasonably represents the most unfavorable instability state for this type of structures.

ABSTRACT: This article investigates the nonlinear vibration behavior of multiscale composites nanoshells subjected to hygrothermal environment and resting on elastic foundations. The novelty and contribution of this article is considering a multiscale doubly curved sandwich nanoshell. Three-phase composite nanoshell...
composes of polymer-Carbon nanotube-fiber (PCF) and polymer-Graphene platelet-fiber (PGF) according to Halpin-Tsai model. Various distributions patterns such as U (uniform), X, A and O are considered. The classical shell theory and nonlocal strain gradient theory including von Kármán strain–displacement relationships are employed to build the size-dependent governing equations. The governing equations of multiscale nanoshell have been implemented by Hamilton's principle and solved by homotopy perturbation method. For investigating correctness and accuracy, this paper is validated by other previous researches. Finally, the effects of different parameters such as temperature rise, various distributions patterns and curvature ratio have been investigated.

ABSTRACT: The present article proposes an advanced Ritz formulation with 3D capabilities for the analysis of thin-walled metallic and composite beam structures. Various set of admissible functions such as: Legendre, Chebyshev and algebraic polynomials, as well as hybrid functions are employed. The investigation is carried out by using the method of power series expansion of displacement components based on 2D-Taylor polynomials. The governing equations (GEs) are derived in their weak form via Hamilton’s Principle and are solved by using the Ritz method. Convergence and stability of both cross-section and admissible functions have been thoroughly analysed. The high level of accuracy of the proposed formulation has been comprehensively examined in three selected case studies: (i) slender beams with arbitrary boundary conditions, and both solid and thin-walled cross-sections; (ii) a fully-clamped three-layer non-homogenous circular cylindrical shell; (iii) a fully-clamped functionally graded material (FGM) box resting on two-parameter elastic foundation.

ABSTRACT: This work aims to study the effect of oblique stiffeners on the nonlinear static and dynamic buckling behaviors of S-FGM cylindrical panels based on the classical shell theory (CST) with the geometrical nonlinearity in von Kármán Donnell sense. The dynamic critical buckling load is obtained by Budiansky-Roth criterion. The cylindrical panels are reinforced by oblique stiffeners on the top layer, and supported by elastic foundations on the bottom layer. Numerical results are given to evaluate effects of inhomogeneous, dimensional parameters, temperature increment, compressive pressure, oblique angles of stiffeners, the imperfection of original shape, and elastic foundations to the nonlinear static and dynamic response of S-FGM cylindrical panels in the thermal environment.

ABSTRACT: Based on Reddy’s third order shear deformation shell theory and Galerkin method, this paper introduces analytical solutions to study nonlinear buckling behaviors of imperfect carbon nanotube reinforced composite cylindrical panels on elastic foundations in thermal environments. The panels are reinforced by single-walled carbon nanotubes and the eccentrically longitudinal and transversal stiffeners. The effects of geometrical parameters, eccentrically stiffeners, elastic foundations, initial imperfection, temperature increment and nanotube volume fraction on the mechanical behaviors of the nanocomposite cylindrical panels are also examined in numerical results. Some comparisons with results of other authors show the accuracy of the present theory and approach.

ABSTRACT: This article contains examples to demonstrate the use of different design concepts for cylindrical shells under axial compression. The examples are based on shells which were manufactured according to electroplating, machining, welding (isotropic cylinders) and prepreg hand layup on a mandrel (composite cylinders). Three of the four shell series are characterized by pure elastic buckling and one shell series buckled in the elastic-plastic region. All relevant data for the numerical analysis are described in the article and summarized in the Elsevier repository of this article (geometry, material, measured imperfection data and Python-ABAQUSS scripts).

The design concepts are based on the geometric imperfection signatures, probabilistic and deterministic lower-bound methods. The design concepts are representative for the development of design approaches for imperfection sensitive shells from the early 1980 to the late 2010 and are validated with experimental data. Recently developed design lower-bound curves for axially loaded cylinders are presented and compared with currently used design criteria like the Eurocode EN 1993-1-6 and the NASA SP-8007. The results of this article show that the design of imperfection sensitive cylinders has been significantly improved in the last 30 years. References listed at the end of the paper:

ABSTRACT: Previous studies on the mechanical performance of AH (assembled hub) joints mainly focused on the axial capacity and the bending capacity of the joint system. However, the joint system in latticed shells is subjected to combined axial forces and bending moments in practice. In this paper, the mechanical performance of joints under eccentric load is investigated experimentally and numerically. The eccentric bearing capacity, as well as the failure mechanism of the novel joint system, are derived and compared with the axial loading and pure bending conditions. The correlation curve with 95% guaranteed rate is determined by non-linear regression analysis. On this basis, a combined non-linear spring model is established to simulate the mechanical performance of joints in single-layer cylindrical shells for stability analysis. The results indicate that for orthodox type cylindrical latticed shells with diagonals or crossed cables, the stability reduction factor can reach a range of up to 0.8 to 0.96. However, for cylindrical latticed shells with lamella grids or three-way grids, the stability reduction factor is less than 0.62. This situation can be improved by strengthening the joint system or reducing the intersection angles of members. When the intersection angle decreases from 90° to 60°, the stability reduction factors of lamella shells will increase by 34%–47%. This means that cylindrical shells with AH joints have sufficient stability to meet engineering requirements by rational design.

ABSTRACT: To study the influence of frame-to-plate connections and oblique channel-shaped stiffeners on the seismic behavior of steel plate shear walls (SPSWs), cyclic quasi-static tests were carried out on two one-bay two-story specimens. One specimen was diagonally stiffened with two rectangular openings, and the other was multi-obliquely stiffened with one rectangular opening. The bearing capacity, ductility, degradation characteristics, and energy dissipation of two specimens were analyzed. Furthermore, following the test program, the stress distribution, deformation and fracture tendency of the two specimens were simulated by the finite element (FE) software ABAQUS and validated by the experimental results. The experimental results show that the channel-shaped stiffeners make full use of the larger flexural and torsional stiffness and improve the bearing capacity, stiffness, and elastic buckling load of the structures. Moreover, the oblique stiffeners have an obvious bracing effect, so the web of the middle beam is subjected to shear yield at the opening segment, which is similar to the link in the eccentrically braced frame. The inelastic mechanism is transferred from the steel plate to the link. In the plastic stage of the structure, the stiffened plate is basically elastic, and the seismic energy is mainly consumed by the link. Therefore, this kind of steel plate shear wall needs to consider the additional effect of the stiffeners on the boundary elements. The reasonable design of the link segment enables the frame to have enough strength to support the stiffened plate as well as avoid premature yielding at the link.

ABSTRACT: In this paper, a finite element analysis based systematic parametric study has been conducted on perforated Lean Duplex Stainless Steel semi-elliptical hollow section members subjected to torsion. Upon validation of finite element modelling procedure with experimental results, a parametric study was conducted on members with single circular perforation, on either flat or curve element of semi-elliptical hollow section. The diameter of the perforation was varied from 10% to 90% of the flat element length. Five different failure modes were identified for perforated members and reported in this study. The finite element results generated from the parametric study were further used to propose design equations. Initially, design equations for unperforated members were proposed in three different formats – (a) Direct Strength Method, (b) European code and (c) Deformation Based Method (in line with Continuous Strength Method). A reduction factor, expressing as a function of both cross-section slenderness and perforation diameter, was incorporated to extend these proposed design equations to perforated members. Efficacy of all proposed design rules were assessed by conducting reliability analysis.

ABSTRACT: In this paper a mixed finite element based on Generalised Beam Theory (GBT) is proposed to analyse the first-order behaviour of naturally curved beams with circular axis (without pre-twist) and having deformable thin-walled cross-sections. The element applies the assumed strain concept to the longitudinal strains terms that are not present in straight members and cause locking. The additional strain DOFs are condensed out and therefore the stiffness matrix of the mixed element shares the DOFs of the standard (displacement-based) GBT finite element. The superior predictive capacity of the proposed mixed element with respect to the standard element with reduced integration is demonstrated through several examples involving complex global-distortional-local cross-section deformation.

ABSTRACT: Triangular lattices were hierarchically incorporated into a regular hexagonal honeycomb to substitute each vertex of the regular honeycomb. To investigate the crushing behaviors of the newly constructed vertex-based hierarchical honeycombs, finite element (FE) analyses were carried out subsequently for both in-plane and out-of-plane crushing. Effect of the hierarchical organizational parameter on deformation mode, crushing response and energy absorption capacity were discussed respectively. The results showed that the hierarchy significantly affected the crushing behaviors of the honeycomb differently for in-plane and out-of-plane crushing. The hierarchy had a far greater influence on the deformation mode for in-plane crushing than out-of-plane crushing. Compared with that of the regular honeycomb, hierarchy not always improved the honeycomb in terms of plateau stress and specific energy absorption (SEA). The maximum plateau stress and SEA of the hierarchical honeycombs increased by up to approximately 127% and 109% respectively under crushing along L direction (in-plane ribbon direction); 122% and 108% respectively under crushing along W direction (in-plane width direction); and 30% and 34% respectively under crushing along T direction (out-of-plane direction).

ABSTRACT: Above-ground pipeline systems are subject to a wide range of deformations, such as ovalization and warping, particularly in the neighborhood of a support. A structural analysis, which can fully evaluate these transversal and local effects, can currently be carried out only using shell or solid finite-element models. However, the complete finite-shell element model of a long-distance pipeline system requires a significant amount of time to be modeled and solved. In contrast, generalized beam theory (GBT) has attracted attention as an alternative modeling technique, and it can easily model a pipeline system using beam-finite elements, but with all transversal and local effects. In order to obtain a feasible application of GBT for above-ground pipeline systems, this study presents an extension of GBT with semi-continued arbitrary support to hollow circular cross-sections. The numerical formulation is an alternative recursive approach based on the master-slave method to create a multi-freedom constraint among the high modes of GBT and the springs, which represent the support conditions. An example of its application illustrates the proposed approach and is compared with a complete finite-shell element models.

ABSTRACT: This paper aims to develop design methods for the shear strength of welded stainless steel I-shaped members. The current American AISC Design Guide 27 has been published for Structural Stainless Steel, and it refers to the specification ANSI/AISC 360-16 for structural steel buildings for the shear strength without considering tension field action (TFA). All the available test data on stainless steel plate girders were collected from literatures and employed to assess the provisions in the Design Guide 27, as well as the codified ones in Eurocode 3 Part 1.4. Based on the test results and obtained comparisons, two new proposals for unstiffened webs or webs with transverse stiffeners widely spaced (without TFA), and for interior webs with stiffeners spaced at $3h$ or smaller (considering TFA) were developed and presented to match the format of the expressions in ANSI/AISC 360-16 for stainless steel webs under shear. Reliability analysis was further performed to calculate the Load and Resistance Factor Design (LRFD) resistance factors determined by the new proposals and to further justify the target factor in AISC Design Guide 27 for structural stainless steel.

ABSTRACT: This study presents a novel non-local model for the stress analysis of sandwich plates with a functionally graded core using Peridynamic Differential Operator (PDDO) and Refined Zigzag Theory (RZT). The through-thickness material properties of the functionally graded cores were tailored by means of mixing rules. The PDDO converts the equilibrium equations of the RZT from the differential form into the integral form. This makes the PDDO capable of solving the local differential equations accurately. The RZT is very suitable for the stress analysis, especially for thick and moderately thick plates. It contains only seven kinematic variables and eliminates the use of the shear correction factors. A typical sandwich structure consists of a soft core and stiff orthotropic face-sheets. The mismatch of the stiffness at the core and face sheet interfaces results in an increase in the interfacial shear stresses, leading to the core-face sheet delamination. The interfacial stresses can be mitigated by functionally grading the material properties of the core through the thickness. The PD-RZT stress and displacement predictions were compared with the analytical solutions by using the uniform and non-uniform mesh discretizations and good agreements were achieved. It was observed that the functionally graded cores offered some advantages with respect to the classical cores and minimized the stress concentrations at the interface of the core and the face sheets.

ABSTRACT: The work herein presented is devoted to the prediction of the ultimate response of high-yielding low-hardening aluminium alloy beams subjected to a moment gradient. To this scope, a wide parametric analysis has been performed by the ABAQUS computer program to investigate the response parameters characterising the ultimate behaviour of I-beams. The parameters affecting the ultimate performances of aluminium alloy I-beams subject to local buckling under non-uniform bending are the flange slenderness, the flange-to-web slenderness ratio and the non-dimensional shear length. The flange slenderness parameter is directly related to the occurrence of local buckling either in the elastic or in the plastic range. The flange-to-web slenderness ratio accounts for the interactive buckling of the plate elements constituting the member section. The non-dimensional shear length accounts for the longitudinal stress gradient due to non-uniform bending. These non-dimensional parameters define entirely the geometry of the three-point bending scheme usually adopted for evaluating the rotation capacity of metal members. The results of the parametric analyses are expressed by the moment-rotation curves whose response parameters are the subject of empirical formulations. The final goal is the setting up of formulations to predicting both the maximum bending resistance and the rotation capacity of aluminium beams made of high-yielding low-hardening alloys.

ABSTRACT: This paper presents the behavior of fiber-reinforced polymer (FRP)-confined concrete-filled stainless steel tube (CFSST) stub columns under axial loading. Six CFSST stub columns and 18 FRP-confined CFSST stub columns were tested. Typical failure modes and load–displacement curve were obtained. The effects of the number of carbon FRP (CFRP) wrapping layers and the thickness of the stainless steel tube were analyzed. In contrast to the uniform outer buckling of CFSST specimens, all FRP-confined CFSST specimens were found with the first explosive rupture of the CFRP wrap in the midheight region. Typical axial load–displacement curve exhibited four stages, namely, elastic, secondary ascending, repeated fracture, and post-fracture stages. All CFSST and FRP-confined CFSST specimens underwent substantial hardening after the yielding of composite sections. With the confinement of wrapped CFRP, the load-bearing capacity of FRP-confined CFSST specimens was increased by up to 71.35%, and the energy absorption capacity was also enhanced considerably. Test results indicated that the improvement in the load-bearing capacity approximately increased linearly with the number of CFRP wrapping layers, and the load-bearing capacity increased with confinement ratio (math/math). Based on the trend line of the increase in load-carrying capacity versus confinement ratio (math/math), a simplified method was proposed to predict the capacity of FRP-confined CFSST stub columns. This simplified method conservatively predicted the experimental results, warranting its further application in the field of engineering.

ABSTRACT: The research introduces a unified method to investigate the dynamic behavior of spherical caps with uniform and stepped thickness distribution under different edge constraints. In the framework of thin shell theory, the mathematical model of spherical cap is proposed. By combining the multi-section partition technique and
Rayleigh-Ritz method, the vibration characteristics of spherical caps can be obtained. The spherical cap is partitioned into sections along the meridian direction, in which the displacement components of spherical caps along meridian and circumferential direction are respectively represented by Jacobi polynomials and Fourier series. Based on the virtual boundary spring stiffness technique, different edge conditions can be easily simulated. The comparison with FEM, modal test and published literatures prove the accuracy and dependability of current method. The impacts of geometric parameters and edge constraints on the vibration characteristics of spherical cap are also discussed.

ABSTRACT: Thin shells are increasingly finding new applications under the sea. In this study, we consider a thin-walled shell-of-revolution assembly comprising a deep spherical shell dome (deeper than a hemisphere) axisymmetrically and tangentially joined to a steep-sided conical shell, the whole being a closed shell structure intended for stationary deployment beneath the surface of the sea in relatively shallow water. The closed shell structure, which might serve as an underwater observatory, is intended to operate at a constant depth, anchored to the seabed against flotation forces, with the thin steel shell walls being required to withstand the external hydrostatic pressure of the surrounding water. We use shell theory to investigate the discontinuity stresses that occur at the junction of the spherical shell and the conical shell, and employ FEM to explore the buckling behaviour of the thin shell. While discontinuity stresses are relatively small, they may influence the lower buckling modes of the shell, which are found to be largely confined to the region of the cone that is adjacent to the junction. Considerations are extended to a doubly-curved variant of the cone in the form of a paraboloid of revolution. As expected, double curvature enhances buckling capacity and also influences the mode shapes.

ABSTRACT: Although the use of longitudinal stiffeners in cold-formed steel members in compression is known to increase their ultimate strength at ambient temperatures, it is expected that the rigidity of such stiffeners and the strength of steel decreases when the cold-formed steel members are exposed to high temperatures. Therefore, this paper presents and discusses the results of an experimental investigation on the structural response of cold-formed steel columns with intermediate and edge stiffeners under fire conditions for assessing mainly their critical temperatures, critical times (fire resistance) and failure modes. The main variables studied included the: (a) cross-section shape, (b) boundary conditions, (c) edge stiffener configuration and (d) stiffness of the surrounding structure to the thermal elongation of such columns. Additionally, European fire design predictions (EN 1993-1-2:2005) were compared with the experimental results, in order to observe their accuracy. Finally, based on the findings of this research work it is obvious the advantage of using CFS sections with double edge fold stiffeners over the sections with single edge fold stiffeners. Moreover, built-up sections had lower critical temperatures than those for single sections, but with slightly higher fire resistance.
time. Furthermore, existing analytical methods have been shown to be incapable to predict sufficiently realistic
the complex buckling behaviour of restrained CFS columns under fire conditions.

Announcing the launch of our new product, the "SmartGauge" system, designed to revolutionize the measurement industry.

The SmartGauge is a cutting-edge solution that combines high-precision sensors with advanced data analysis software to deliver unparalleled accuracy and efficiency in various applications. It is designed to meet the needs of professionals in sectors such as manufacturing, construction, and research.

Key Features:
- High-precision sensors for accurate measurements
- User-friendly interface for easy operation
- Customizable software for specific requirements
- Real-time data analytics for informed decision-making

Applications:
- Manufacturing: Quality control, process optimization
- Construction: Structural integrity checks, building compliance
- Research: Material science, environmental monitoring

Benefits:
- Increased productivity and efficiency
- Enhanced product quality and safety
- Cost savings through reduced waste and errors

Order now and experience the future of precision measurement technology. Contact us for a free consultation to explore how the SmartGauge can benefit your business. 

SmartGauge - Precision at your fingertips.
geometric imperfections depending on welding variables. Manufacturing imperfections are calculated for several girders with different corrugation profiles. The obtained tendencies are evaluated and discussed in the current paper (Part I). In the accompanying paper [1] (Part 2) the effect of manufacturing imperfections are analysed on the shear buckling resistance of corrugated web girders. The whole numerical simulation process from manufacturing simulation to resistance determination is presented, and their advantages in the design are demonstrated.

ABSTRACT: Plastic forming technology is a low-cost and high-efficiency way to produce doubly curved sandwich plate from a flat plate. However, there are various potential forming defect modes which may affect the formability of sandwich plate. This paper is focused on the defect-free plastic forming of all-metal sandwich
plates with bi-directionally trapezoidal cores, an approximate theoretical model for predicting the global buckling of sandwich plate was developed and the formability of sandwich plate with different geometric parameters were investigated analytically, experimentally and by numerical simulations. The results show that the forming defect mode which dominates the formability of a specified sandwich plate depends on the geometric parameter of the sandwich plate, the formability of the thin sandwich plate with small size core cells is limited by global plastic buckling, while that of the relative thick sandwich plate with relative large size core cells is limited by skin wrinkling and skin dimpling. Significant trends are found that the sandwich plates with thick skins have superior forming performance compared to those with thin ones, and that the limit forming radius is decreased greatly with the decrease of the characteristic sizes of core cell unit. Multi-point forming experiments on bi-directionally trapezoidal sandwich plates were performed, and the numerically simulated results and theoretically analyzed results on the formability were demonstrated finally.

ABSTRACT: In order to balance the strength and weight, 3D lightweight metallic kagome lattice sandwiches were fabricated by selective laser melting with 304 stainless steel (SS) and Co-Cr-Mo (CCM) alloy. Systematical experiments, numerical modeling and theoretical prediction for compression and bending behaviors were conducted. The experimentally measured strengths are very close to the theoretical predictions, demonstrating the excellent mechanical properties. The numerical modeling can capture the stress-strain, load-deflection curves, and the failure mode is the strut buckling initiated from the plastic hinges with high stress level. The CCM alloy kagome lattice sandwich presents non-synchronous deformation. The buckling of the struts near bottom facesheets always arises first, and is followed by the subsequent buckling of the struts near up facesheets. The strength and modulus of CCM alloy are higher than those of 304 SS, resulting in relative high values of strength and load capacity for CCM alloy kagome lattice sandwich. In contrast, the superior plasticity of 304 SS enables relative high plastic deformation ability of 304 SS kagome lattice sandwich. The kagome lattice sandwiches provide a solution to effectively balance the strength and weight, as they present lower density than engineering alloys and higher strength than honeycombs, foams and pyramid lattice sandwich.

ABSTRACT: A localized nanostructuring approach is proposed to manufacture bistable metallic shells and improve bistable properties of conventional cylindrical bistable shells. The stable configurations and transition processes of bistable shells based on three different mechanisms are experimentally and numerically investigated. Compared to conventional bistable cylindrical shells produced by plastically bending, the bistable shells with a nanostructured region can have much higher load bearing capacities and stiffness, and consume more energy before shape transition, no matter in a domelike shape or a cylindrical shape. Numerical modelling is developed using two equivalent inelastic strains for the plastic bending deformation and accumulated plastic deformation in nanocrystallization process. For nanostructured bistable shells, the internal stress fields are found to play important roles for the transition features, which are considerably affected by eccentric loading, while the eccentric loading has little effect on transition processes of the cylindrical bistable shells made by plastically bending. The influences of the size of the nanostructured region, the plate thickness and different nanostructuring processes on the bistable behaviors are further experimentally studied. In addition, the bistable properties of the bistable shells based on different mechanisms after thermal treatment from 200°C to 700°C are investigated. The applied nanostructuring process largely improves the bistable properties of bistable metallic shells, which can sustain severe environment of high temperature (about 500°C).

ABSTRACT: The analytical approach is presented to study the nonlinear vibration of W-Cu sandwich shell containing heavy water surrounded by an elastic foundation under thermo-mechanical loads. The cylindrical shell is assumed to be made of Tungsten and Copper, continuously graded in the thickness direction. The fluid in the shell is heavy water which is assumed to non-viscous and incompressible. The nonlinear vibration of the full-filled fluid shell using Flügge-Lur'e-Bryrne theory is investigated through the Galerkin method. The natural frequencies, the dynamical responses as time history and phase plane graphs, Poincaré map are given in detail. The obtained results that are validated with other studies, have the valuable applications in nuclear reactors, rocket shells, fusion reactor vessels.

ABSTRACT: The nonlinear primary resonances of symmetric rectangular honeycomb sandwich panels with simply supported boundaries along all four edges are studied. The nonlinear governing equations of the symmetric rectangular honeycomb sandwich panel subjected to transverse excitations are derived by using Hamilton's principle and Reddy's third-order shear deformation theory. These nonlinear partial differential equations are reduced into nonlinear ordinary differential equations by the Galerkin method. Based on the homotopy analysis method, the average equations of the primary resonance are obtained. For all the three primary resonances cases, the frequency-response curves of primary resonance are constructed. Comparison studies on the forced vibration of cubic non-linearity system are conducted to verify the correctness and accuracy of the homotopy analysis method. Effects of thickness-to-length ratio, width-to-length ratio and transverse excitation on the nonlinear primary response have been investigated for honeycomb sandwich panels.

ABSTRACT: Double-corrugated-plate shear wall (DCPSW), which is composed of two identical corrugated plates and assembled by connecting bolts, is an innovative type of lateral force resistant device for high-rise building structures. In this paper, the shear resistant behavior of the DCPSW is investigated via tests and additional finite element (FE) parametric study. First, the test results of two DCPSW specimens subjected to monotonic in-plane shear loads are reported. Second, FE models are introduced to perform simulations on the shear resistant behavior of the test specimens; it is seen that the numerical results fit well with the test results, and hence the FE models for simulations of the DCPSWs are validated. Then, an additional parametric study is presented by changing the geometrical parameters including aspect ratio, bolt column number, corrugation amplitude and dimensions of boundary elements of the DCPSWs. As a result, the effects of these parameters on...
the shear resistant behavior of the DCPSWs are further revealed. It is shown that the ultimate shear resistance of the DCPSWs increases with the increase of aspect ratio, bolt column number and corrugation amplitude, yet the dimensions of the boundary elements have little effect on the shear resistance of the embedded corrugated plates. Finally, by analyzing the results of the parametric study, some design remarks are concluded to provide valuable references for the design of the DCPSWs in practice.

ABSTRACT: In this paper, an efficient simple numerical method, known as energy-based collocation, is presented to analyze the nonlinear behavior of a geometrically imperfect composite plate subjected to compressive in-plane load while taking into account progressive damage phenomena. This method is based on the energy approach, in which the plate is discretized into the Legendre-Gauss-Lobatto points. The nonlinear governing equations are based on the First-order Shear Deformation Theory (FSDT) and the assumptions of large deflection. The system of nonlinear algebraic equations is solved using the quadratic extrapolation technique. Plates with various boundary conditions and different ranges of thickness are investigated. Hashin and Rotem failure criteria are established to predict failure. Several properties degradation models are proposed for the developed failure mechanism and description of ply degradation. The analysis is performed by a computer program developed based on FORTRAN language. The accuracy of the developed procedure is assessed by comparing numerical results taken from previous works.

ABSTRACT: Structural responses, deformation modes, blast resistance and energy absorption of foam core signify some major functional characteristics for design of sandwich panels. This study aimed to address these issues by investigating uniform and graded foam core configurations. First, an experimental study was performed and the testing results of blast-loaded sandwich panels were analyzed. Second, a numerical model was developed and validated by comparing the simulation results with the experimental results in terms of deformation modes and back facesheet deflection. Third, the blast resistance of sandwich panels was comprehensively studied based upon the developed numerical models. Due to the high attenuation ability of the shock induced stress wave, the foam core with descending gradient of layer density across the thickness direction provided the highest blast resistance of all the core configurations considered here and its advantage could be further improved by enlarging the density difference of the core layer. While keeping total facesheet thickness unchanged, a relatively thick back facesheet is beneficial to enhance the blast resistance under relative low blast intensity. Finally, an optimization study was performed to improve the blast resistance of graded core sandwich panels. For the single objective optimization, the maximum back facesheet deflection of the optimum design decreased by 24.58% in comparison with that for the initial baseline design. For the multiobjective optimization, the optimal designs obtained from the Pareto solution can significantly enhance weight efficiency without compromising the resistance.

ABSTRACT: Concrete-filled aluminum tubular (CFAT) columns have the advantages of a lightweight, high resistance to corrosion, good appearance and ease of maintenance over concrete-filled steel tubular (CFST) columns. However, experimental and computational studies on the performance of CFAT columns have rarely been reported. This paper concerns with the fiber-based numerical analysis, structural behavior, and design of circular high strength CFAT stub columns loaded concentrically. A new concrete confinement model for computing the lateral pressures on the concrete core in CFAT circular columns is proposed and implemented in the computational model. The numerical analysis procedure is given for the determination of the nonlinear load-strain behavior of CFAT stub columns. The available experimental results of circular CFAT columns are used to assess the accuracy of the developed model. The computer model is employed to ascertain the significance of various geometric parameters in addition to material strengths on the responses of CFAT stub circular columns. The design equation based on Liang-Fragomeni's expression is proposed for quantifying the ultimate axial strengths of axially compressed CFAT short columns. The verification reveals that the computer modeling approach accurately quantifies the ultimate loads and nonlinear load-strain performance of CFAT columns with circular sections. The proposed design equation yields good calculations of the ultimate axial strengths of CFAT columns.

ABSTRACT: This paper investigates the dynamic instability of a functionally graded porous arch reinforced with uniformly distributed graphene platelets (GPLs) under the combined action of a static force and a dynamic uniform pressure in the radial direction. The relationship between the elastic modulus and mass density of the material is determined by the closed-cell cellular solids under Gaussian Random Field scheme. The governing equation is derived based on classical Euler-Bernoulli theory. Galerkin approach is used to derive the Mathieu-Hill equation from which the dynamic unstable region is obtained using Bolotin method. A comprehensive parametric study is conducted to examine the effects of GPL weight fraction and dimensions, porosity distribution, pore size, static force, and arch geometry and size on the dynamic stability characteristics of the arch. Numerical results show that the porous arch's resistance against dynamic instability can be considerably improved by using symmetrically non-uniform porosity distribution and the addition of a small amount of GPLs.

ABSTRACT: Ultra-high performance cementitious composite filled steel tube (UHPCC-FST) has been widely applied as the load bearing members for long-span bridges, which are the potential bomb explosion attack targets in terroristic activities. This paper aims to experimentally study the residual axial capacity of UHPCC-FST columns under contact explosion by conducting the field contact detonation and the subsequent axial compression tests. Firstly, five UHPCC-FST cylinder columns are fabricated with the column height, outer diameter and core concrete compressive strength being 2000 mm, 203 mm and 131.5 MPa, respectively.
Secondly, three of which are tested under contact explosion with the TNT charge weights of 1 kg, 2 kg and 3 kg, in which the impact craters are formed and the integrity of the columns is maintained under 1 kg and 2 kg TNT explosions, while the outer steel tube is seriously ruptured and the core UHPCC is fully crushed for 3 kg TNT explosion. Furthermore, the original axial capacity of intact columns and the residual axial capacity of blast-damaged columns are evaluated though the axial compression tests, and the relationships between the axial load and axial/lateral displacement are derived. It indicates that, (i) both the intact and blast-damaged columns under axial compression show diagonal shear failure, the local bulging of steel tube is induced due to the low confinement of steel tube and high compressive strength of UHPCC; (ii) the quantitative dependence of column damage index on the charge weight is determined.

ABSTRACT: This paper presents a unified theory for the vibrational analysis of thin-walled composite beams (TWCB) with arbitrary planar axial curvature, variable cross section, and general composite material layup, allowing for the accurate modelling of a large class of composite beams with an accuracy normally achievable only through shell-type finite-element (FE) models, but at a fraction of the numerical cost. The kinematic description is based on the Frenet-Serret frame field, providing a transparent path for transforming the equations of motion from rectilinear to curved TWCB while fully accounting for curvature gradient terms, thereby allowing for the treatment of highly curved geometries. Additional innovations include the use of a novel formulation increasing the accuracy for cases with significant axial-bending-torsional structural coupling, as well as a computationally efficient Isogeometric Analysis (IGA) formulation. The new method has been applied to modal and transient analysis of several test cases where conventional TWCB models are found to yield limited accuracy. The results obtained are almost indistinguishable from those obtained with a full-sized shell-based FE model, at a computational cost which is about two orders-of-magnitude smaller.

ABSTRACT: This paper proposes a scheme for distributed piezoelectric actuator layout-design to improve active vibration control performance of thin-walled smart structures. The aim of the design is to maximize the energy transformation from actuator to structure so that better control performance will be achieved under a control strategy. The system performance index (SPI) is used to measure energy transformation. The layout-design problem is formulated by combining the topology optimization technique and the SPI. The pseudo-densities of piezoelectric materials are used as design variables and a penalty function is applied on piezoelectric materials so that a clear result can be obtained. Based on the chain rule and the adjoint method, and with the help of solving Lyapunov function, the sensitivity analysis is conducted. The optimization model is solved by nonlinear programming method. Once the optimized layout is obtained, the linear quadratic regulator (LQR) control strategy is applied and vibration suppression can be achieved. The method is load-independent. External loads and control strategy are not considered in layout-design so that a single layout can be obtained.
Yet for all that, the optimized layout can achieve excellent performance in a wide range of load cases. Two numerical examples and two engineering applications demonstrate the validity of the proposed method.

ABSTRACT: Although it is well known that initial deflections have a significant influence on load-bearing capacity of unstiffened square box section columns under axial compression, their quantitative influence is not clear. In this study, 378 finite element models were analyzed to reveal the quantitative influence of local and overall initial deflections on load-bearing capacity. In the parametric analyses, nine combinations of the amplitude of the local and overall initial deflections were considered. In addition, normalized width-thickness and slenderness ratios were varied with ranges from 0.3 to 1.8 and from 0.3 to 1.5, respectively. As a result, the initial deflection influence coefficient was proposed to describe the quantitative influence on load-bearing capacity and formulated as functions of the local and overall initial deflections, normalized width-thickness and slenderness ratios. The accuracy of the proposed formula was verified through the comparison with the FEA results including additional 108 FEA results with normalized slenderness ratio of 0.9 and 1.2.

ABSTRACT: The current slenderness limits are significantly different in international design codes for cold-formed Circular Hollow Sections (CHS) under pure bending. This paper aims to use the Finite Element (FE) method to understand the behaviour of cold-formed CHS under pure bending and to propose new design rules. The model is calibrated by comparing its predicted load-deflection curves with previously published experimental data. In total, 21 specimens were modelled with diameter-to-thickness ratios ranging from 13 to 122. The current slenderness limits in the present international steel specifications were examined using the FE model and their suitability for cold-formed CHS is discussed. The effect of section slenderness on rotation capacity has been examined where the predicted variation of rotation capacity against section slenderness has been compared to the experimental results. A new equation for the amount of initial geometrical imperfection as a function of section slenderness has been developed and proposed for design purposes. The ovalisation deformation ratio and the critical strain at local buckling were determined and compared for compact, non-compact and slender sections. The progressive bending deformations of CHS at 10 critical steps have been presented and compared for the three cross sectional types, in particular at the maximum moment and bending rotation. In general, a good agreement has been obtained between the predicted strengths and ductilities using the current FE models and those of the experimental data of cold-formed CHS.

https://doi.org/10.1016/j.tws.2019.106544

ABSTRACT: By means of combining Flügge's thin shell theory and energy method, a generalized approach to investigate vibration characteristic of truncated spherical shell subjected to various edge constraints is proposed. The truncated spherical shell is devided into different sections along the meridian line, in which the displacement function of truncated spherical shell along meridian and circumferential line are respectively represented by Jacobi polynomials and Fourier series. Various edge constraints can be simulated on the basis of virtual spring stiffness method in the current research. Finally, the solutions can be derived by mean of Ritz method. The dependability and exactness of current method have been proved by the comparison between
current method, FEM and related literatures. The dimensionless frequency parameters of different truncated spherical shell under various edge constraints are displayed. In addition, the influence of geometric dimensions and boundary constraints on frequency parameters are also discussed.

ABSTRACT: For the preliminary structural design of aircraft, spacecraft and marine vessels, computationally efficient and sufficiently accurate computational methods are necessary. The present work contributes to this field by deriving a new closed-form analytical solution for the local buckling analysis of omega-stringer-stiffened composite panels. Hereby, the plates of the assembly are modelled separately and include the stiffener foot. The principle of the minimum potential energy is used in a Ritz-like approach and leads to an explicit analytical formulation of the critical buckling load. The compliance to geometric and dynamic boundary conditions is ensured. The panel is uniaxially loaded and investigated for different geometrical and material configurations. For the verification of the presented method, a finite element analysis is performed as well as a solution of the Lévy type is obtained. Very good agreement of the new closed-form analytical approach with finite element analyses is shown in numerical studies for technical relevant areas of the design space.

ABSTRACT: Thin-walled cylindrical structures are widely used in aerospace, offshore, civil and other engineering fields. Parts of space launcher transport systems are one example for the application of such shells. Buckling of thin-walled structures is a very important phenomenon to be considered during their design phase. This is true not just because such structures are often imperfection sensitive (geometry, boundary conditions, load introduction, thickness, etc.) but also due to operational requirements set on these thin-walled structures which often lead to the need for introducing cutouts to accommodate access panels, doors and windows. These cutouts constitute an additional factor that influences the overall stability and needs to be understood in order to enable a safe operation and an effective design of these structures. The study deals with buckling experiments on two axially compressed, unstiffened CFRP cylindrical shells with circular unreinforced cutouts, performed by DLR. Moreover, a FE model is described that is validated with the experimental results. The objective of the study is to investigate the effect of the size of the cutouts on the buckling characteristics of the tested shells.

Shengwen Tu and Jian Shuai (Faculty of Safety Science and Ocean Engineering, China University of Petroleum (Beijing), 102249, Beijing, China), “Numerical study on the buckling of pressurized pipe under eccentric axial compression”, Article 106542, Thin-Walled Structures, Vol. 147, February 2020, https://doi.org/10.1016/j.tws.2019.106542

ABSTRACT: Pipeline transport is one of the main solutions for oil and gas transmission and distribution. The pipeline in service may be subjected to complicated loads (internal pressure, tension or compression, bending and their combination) when crossing complex geohazard regions. In this study, the compressive strain capacity of pressurized pipelines under eccentric axial compression is investigated numerically. Meanwhile, the effects of the internal pressure, pipe diameter-to-wall-thickness ratio (D/t) and the material strain hardening capacity on the compressive strain capacity are studied. It has been found out that under eccentric axial compression, the buckling behavior of pipes depends on the internal pressure, D/t and material strain hardening capacity. The compressive strain capacity increases with the increase of the internal pressure and the strain hardening capacity; while the diameter-to-wall-thickness ratio displays a negative effect.

“Determining inherent deformations of HSLA steel T-joint under structural constraint by means of thermal elastic plastic FEM”, Article 106568, Thin-Walled Structures, Vol. 147, February 2020,
https://doi.org/10.1016/j.tws.2019.106568
ABSTRACT: The inherent strain method is a powerful and efficient tool to simulate welding deformation, so it recently becomes the mainstream way to estimate the total welding distortion of large complex welded structures. When using this method to predict welding deformation, the simulated result strongly depends on the accuracy of the inherent deformations of each typical joint involved in the welded structure. During welding process, the constraint condition usually has a significant influence on the inherent deformations of a welded joint. In the current study, the influence of different constraint conditions on the inherent deformations of atypical high strength low alloy steel thin-plate T-joint was investigated experimentally and numerically. Meanwhile, the welding deformation of a simple thin-plate stiffened-panel structure was calculated by using the inherent deformations of T-joints with different constraint conditions. Based on the simulated results, the influence of the inherent deformations of T-joints with different restraint conditions on the total welding deformation of the stiffened-panel structure was clarified. In addition, a newly method was proposed to obtain the inherent deformations of a welded joint with structural constraint condition.

Bing Du, Jun Xie, Han Li, Changcai Zhao, Xin Zhang and Xiaoming Yuan (Key Laboratory of Advanced Forging & Stamping Technology and Science (Yanshan University), Ministry of Education of China, Qinhuangdao City, 066004, PR China), “Determining factors affecting sheet metal plastic wrinkling in response to nonuniform tension using wrinkling limit diagrams”, Article 106535, Thin-Walled Structures, Vol. 147, February 2020, https://doi.org/10.1016/j.tws.2019.106535
ABSTRACT: In thin plate plastic forming, the efficient, accurate prediction and control of wrinkling is a basic requirement. Because there is no clear means of determining the main strain space curve (similar to the fracture forming limit diagram) when establishing the critical wrinkling state, this work used diagonal tensile plate tests to verify a numerical simulation of plastic wrinkling in thin plates. This model included a buckling mode
As for the effect of temperature distribution patterns in the columns on the member critical temperature, it was one of the important factors that could be detrimental to the fire resistance even with a low load ratio. It was also found that creep deformation associated with the low heating rate decreased the fire resistance of the columns considerably. For those columns with an applied load ratio lower than 0.6, the load ratio led to a significant decrease in the member critical temperatures. The test results indicated that increasing the ambient temperature was tested first. The effects of heating rate, load ratio, and temperature distribution pattern on the fire responses of the columns were investigated in the fire tests. The test results showed substantial improvements from a crashworthiness viewpoint. The obtained interesting results showed the high potential of the BESO algorithm for the design of thin-walled square tubes subjected to an axial crushing load was carried out to enhance its crashworthiness performance, utilizing the modified Bidirectional Evolutionary Structural Optimization (BESO) procedure. In this way, by systematic searching, topology optimization finds the best material layout for the structure to satisfy the objective function. In each iteration, a new pattern of material-void through the tube walls can trigger various folding mechanisms. Thus, the energy absorption history trend might not be smooth and the ultimate pattern proposed by the algorithm is less likely to be the optimal one. With an emphasis on the BESO hypothesis regarding direct removal and addition of elements, the modified BESO algorithm excavated the optimal design in two steps. First, material-void patterns were produced, considering specific energy absorption as the element efficiency criterion. Then, the pattern with the least material usage which satisfies an energy absorption constraint was selected as the optimal design. Such an optimum layout also boosts the tube performance respecting peak crushing force, since the embedded voids through the structure serve as a crush initiator. The optimization code was developed in MATLAB, which was automatically integrated with ABAQUS software performing the nonlinear crushing analysis. To validate the finite element model, an experimental investigation was carried out on a simple square tube. Having performed the topology optimization and some fine-tuning process, the topologically optimized tube was constructed and experimentally tested. Results showed 16.21% weight reduction enriched with 36.57% enhancement in the peak crushing force by sacrificing less than 3.5% energy absorption, which represents substantial improvements from a crashworthiness viewpoint. The obtained interesting results showed the high potential of the BESO algorithm for the design of thin-walled structures under large deformation and out-of-plane buckling.

Jingjie Yang, Weiyong Wang, Yu Shi and Lei Xu (School of Civil Engineering, Chongqing University, Chongqing, 400045, China), “Experimental study on fire resistance of cold-formed steel built-up box columns”, Article 106564, Thin-Walled Structures, Vol. 147, February 2020, https://doi.org/10.1016/j.tws.2019.106564

ABSTRACT: Cold-formed steel built-up box columns are commonly used in mid-rise cold-formed steel buildings to resist applied loads. Numerous studies have been conducted to evaluate the load-bearing capacity of the columns at ambient temperature but there is very limited research on the fire resistance of the built-up columns. In this paper, a full-scale experimental investigation on fire responses of sixteen axially loaded cold-formed steel built-up box columns was conducted. As a benchmark, the load-bearing capacity of the columns at ambient temperature was tested first. The effects of heating rate, load ratio, and temperature distribution pattern on the fire responses of the columns were investigated in the fire tests. The test results indicated that increasing the load ratio led to a significant decrease in the member critical temperatures, which consequently reduced the fire resistance of the columns considerably. For those columns with an applied load ratio lower than 0.6, they were expected to have member critical temperatures higher than 500 °C. Moreover, with thin-walled steel and no fire protection the column temperatures increased quickly, leading to failure in no more than 12 min in a fast fire even with a low load ratio. It was also found that creep deformation associated with the low heating rate was one of the important factors that could be detrimental to the fire resistance and member critical temperature. As for the effect of temperature distribution patterns in the columns on the member critical temperature, it was obtained by an eigenvalue buckling analysis as the initial shape defect in a dynamic explicit numerical simulation of the plastic deformation of the test pieces. This permitted calculation of the true instability morphology of the test piece and avoided the difficulty associated with simulating plastic deformation wrinkling morphologies using existing static implicit or dynamic explicit numerical simulation algorithms. The morphology and characteristics of the critical wrinkling limit diagram (WLD) associated with nonuniform tension were investigated. The effect of the specimen thickness and boundary conditions on the WLD in the main strain space were also examined and the effects of various processing parameters on crease resistance were established. Finally, the effectiveness of the WLD established in this work was verified based on using non-contact full-field strain measurements to examine the plastic wrinkling of thin plates. This research provides a means of establishing the critical wrinkling line for various conditions.

ABSTRACT: In this study, topology optimization of a thin-walled square tube subjected to an axial crushing load was carried out to enhance its crashworthiness performance, utilizing the modified Bidirectional Evolutionary Structural Optimization (BESO) procedure. In this way, by systematic searching, topology optimization finds the best material layout for the structure to satisfy the objective function. In each iteration, a new pattern of material-void through the tube walls can trigger various folding mechanisms. Thus, the energy absorption history trend might not be smooth and the ultimate pattern proposed by the algorithm is less likely to be the optimal one. With an emphasis on the BESO hypothesis regarding direct removal and addition of elements, the modified BESO algorithm excavated the optimal design in two steps. First, material-void patterns were produced, considering specific energy absorption as the element efficiency criterion. Then, the pattern with the least material usage which satisfies an energy absorption constraint was selected as the optimal design. Such an optimum layout also boosts the tube performance respecting peak crushing force, since the embedded voids through the structure serve as a crush initiator. The optimization code was developed in MATLAB, which was automatically integrated with ABAQUS software performing the nonlinear crushing analysis. To validate the finite element model, an experimental investigation was carried out on a simple square tube. Having performed the topology optimization and some fine-tuning process, the topologically optimized tube was constructed and experimentally tested. Results showed 16.21% weight reduction enriched with 36.57% enhancement in the peak crushing force by sacrificing less than 3.5% energy absorption, which represents substantial improvements from a crashworthiness viewpoint. The obtained interesting results showed the high potential of the BESO algorithm for the design of thin-walled structures under large deformation and out-of-plane buckling.
found that the member critical temperatures for specimens with non-uniform temperature distribution were slightly higher than those with uniform temperature distribution.

ABSTRACT: This article investigates the static stability and mode-shapes of composite laminated beams under varying axial in-plane loads. The kinematic displacement field is described by unified higher order shear deformation theory. Six functions are assumed to describe the distribution of axial in-plane load, which are one constant function, two-linear functions, and three-parabolic functions. The Hamilton's principle is proposed to get the equilibrium equations of unified composite laminated beams. An efficient numerical differential quadrature method (DQM) is proposed to solve the govern equations. The obtained equations are solved as an eigenvalue problem to find critical buckling loads and their corresponding mode shapes. The validation studies are compared with published works. Numerical results illustrate effects of in-plane load type, beam thickness, orthotropy ratio, fiber orientations, and boundary conditions on the critical buckling loads. The effect of axial load functions on the buckling mode shapes is presented for the first time. These effects play very important role on the static stability and mode-shapes of composite beam structures. The proposed model may be important in design of aircraft, civil and ship-building when non-uniform in-plane compressive load is important.

ABSTRACT: In this paper, free vibration of thin rectangular plates with cut-outs for different boundary conditions is analyzed by using the discrete singular convolution (DSC) method. First, the entire plate configuration is divided into appropriate sub-domains. The edges involved with cut-outs in each sub-domain are treated as free boundary conditions and the Taylor series expansion method is adopted for solving. Then, the convergence of the DSC method is tested and the frequency parameters were validated by comparing with the exact solutions by Leissa. At last, the influence of rectangular and U-shaped cut-outs structure parameters on the natural frequency is studied.

ABSTRACT: For long-span composite bridges with corrugated steel webs, the encased concrete near the intermediate support section increases the weight of the girder, reduces pre-stressing efficiency, and causes difficulties in the construction process. The authors in the companion paper [1] proposed a corrugated steel web with vertical or/and horizontal stiffeners to replace or shorten the length of concrete encasement. In parallel with experimental study described in the companion paper, this paper further investigates the shear performance of proposed stiffened corrugated steel webs by numerical and analytical methods. Firstly, finite element (FE)
models considering material nonlinearity, welding residual stress, and geometric imperfection were established and validated against the experimental results. Then the effects of web thickness, corrugation depth, height and thickness of stiffeners on shear strength and failure modes were analyzed based on the validated FE models. Finally, both experimental and numerical shear strength were used to evaluate the applicability of existing calculation methods proposed by different scholars to predict the shear capacity of stiffened corrugated steel web. The comparisons reveal that calculation methods proposed by Hassanein & Kharoob [2] and Leblouba et al. [3] predict the shear capacity of pure corrugated steel web more accurately, and all existing calculation methods underestimate corrugated steel web with vertical stiffeners. Therefore, the analytical model for accurately predicting shear strength of stiffened corrugated steel web need to be developed, which will be investigated in subsequent studies.

ABSTRACT: An experimental investigation into the cross-sectional behaviour of hot-finished high strength steel tubular sections, to support the assessment and development of structural design guidance, is presented. Two grades of quenched and tempered high strength steel – S690 and S770 and eight cross-sections – seven square hollow sections (SHS) and one rectangular hollow section (RHS), covering a wide range of local slenderness, were examined. This test programme consisted of twelve tensile coupon tests, five stub column tests and 30 short beam-column tests, with various initial loading eccentricities employed to achieve a spectrum of compression and bending combinations. Local geometric imperfection measurements were carried out on each test specimen using 3D laser-scanning, and a rational approach to analysing the local imperfection distributions using the scanned data was subsequently proposed. Following the experimental study, the current Eurocode 3 cross-section design provisions were evaluated through comparisons with the results from the present research and additional results from the literature. The experimental results and findings from the present study provide a basis for the development of numerical models and the enhancement of existing design methods in the future.

ABSTRACT: An arch under a central in-plane point load may lose its stability in an out-of-plane buckling mode when the load attends a certain value. This paper presents a theoretical study for the out-of-plane buckling of elastic circular arches under a central radial point load using an energy method and an experimental study for the out-of-plane buckling load of elastic circular aluminium arches under a central radial point load. Six circular aluminium arches of doubly symmetric I-sections having different rise-to-span ratios, different load heights and different boundary conditions are tested by applying a radial point load to the crown of the arch. With specially designed supports that can simulate different in-plane boundary conditions, an ingenious loading device and high-precision real-time displacement measurement, the elastic out-of-plane buckling loads of tested arches are accurately recorded. Comparisons show that agreements of test results against theoretical solutions are very good. The influences of the slenderness ratio, in-plane boundary conditions and the load height on the out-of-plane buckling are also investigated and it is found that they influence the out-of-plane buckling load of circular arches significantly.

E. Ozyurt (School of Mechanical, Aerospace and Civil Engineering, University of Manchester, UK and Department of Civil Engineering, Gümüşhane University, Gümüşhane, TR, Turkey), “Finite element study on axially loaded reinforced Square Hollow Section T-joints at elevated temperatures”, Article 106582, Thin-Walled Structures, Vol. 148, March 2020, https://doi.org/10.1016/j.tws.2019.106582
ABSTRACT: This study numerically investigates the elevated temperature resistance of collar plate and doubler plate reinforced Square Hollow Section (SHS) T-joints subjected to brace axial compressive load. The extensive numerical simulations were performed to examine the effects of the geometrical parameters of main members and reinforcing plate on the fire resistance of reinforced SHS T-joints after verification of the numerical models based on the available test results. The corresponding unreinforced joints were also analysed as reference resistance at five different temperature levels (20 °C, 400 °C, 500 °C, 600 °C, and 700 °C). Results indicate that the elevated temperature capacity of SHS T-joints can be significantly increased by using a collar plate or a doubler plate. Although the initial stiffness of the doubler plate reinforced joints was higher than the collar plate reinforced joints, their capacity was similar to each other. Also, the fire resistance of the reinforced joints mainly depended on the brace-to-chord width ratio and reinforcing plate thickness to chord wall thickness ratio. However, there was no beneficial effect on the fire resistance of reinforced joints when the thickness of the reinforcing plate was greater than 1.5 times the chord wall thickness. Moreover, there was an insignificant effect of half-width to thickness ratio of the chord, reinforcing length and reinforcing type as long as the required limit values of the reinforcing length and width were used based on the Eurocode 3 EN 1993-1-8. It is worth mentioning that modifying the steel yield strength in the ambient temperature design method to calculate the capacity of the reinforced SHS T-joints at elevated temperatures may be unsafe. A new design method was developed to predict the capacity of a collar plate and doubler plate reinforced SHS T-joints subjected to brace compressive load in fire.

ABSTRACT: The local buckling behaviour and design of stainless steel plates in fire are investigated in this paper. Finite element models of stainless steel plates able to mimic their response in fire are created and validated against experimental results from the literature. Parametric studies are then performed and the results are utilised to assess the current design provisions set out in the European structural steel fire design code EN 1993-1-2; shortcomings in the prediction of the local buckling response of stainless steel plates in fire are revealed. A new effective width based design approach able to reflect the variation in strength and stiffness of stainless steel at different temperature levels in the determination of the local plate slenderness and thereby the ultimate resistances of stainless steel plates in fire is put forward. The proposed approach is shown to provide significantly higher levels of accuracy and reliability relative to the current provisions in EN 1993-1-2 for a wide range of plate slendernesses, elevated temperature levels, stainless steel grades and loading conditions. The design rules proposed for the local buckling assessment of stainless steel plates at elevated temperatures in this paper are due to be incorporated into the upcoming version of the European steel fire design standard EN 1993-1-2.

ABSTRACT: The pretensioned rectangular membrane is a basic structural component that is widely used in various spacecraft, and requires experimental ground verification before being launched into orbit. However, the dynamic calibration of the membrane is a considerable challenge, because the dynamic response is sensitive to the air resistance effect. A grid membrane can be intuitively thought of as being insensitive to a great extent and proposed as a dynamic equivalent structure. The dynamic equations of the two structures are respectively formulated, and the dynamic equivalent methodology of the two structures is formulated by making the corresponding coefficients of the two equations equal to one another. In the simulations, the frequencies of the two structures under the same vibration amplitude are essentially identical. A low vacuum chamber and biaxial
extension frame are developed for experimental validation. In the experiment, the dynamic response of the grid membrane in air shows a fine consistency with the rectangular membrane in low vacuum. Therefore, the proposed dynamic equivalent methodology is demonstrated to be valid, and the grid membrane can be used as a substitute structure for the rectangular membrane in order to reduce the air resistance effect.

ABSTRACT: Bézier extraction based isogeometric finite element analysis method coupled with a new hybrid type higher-order shear deformation theory (HSDT) is presented for the static bending and buckling analysis of functionally graded carbon nanotube reinforced composite (FG-CNTRC) plates. By mapping non-uniform rational B-spline basis functions to Bézier element in the forms of Bernstein polynomial basis via the Bézier extraction operator, the isogeometric analysis (IGA) can be implemented in the conventional finite element (FEM) framework. This study focuses on the introduction of the Bézier extraction based IGA combined with the HSDT for the static analysis through the formulation and implementation of the second-order derivatives of the Bézier element basis functions, which has hardly been attempted in the open literature. Compared to the conventional FEM based on first-order shear deformation theory, the present IGA method based on the HSDT surmounts the shear locking without exploiting the shear correction factor. The proposed isogeometric approach is thus believed to be more accurate and effective and achieves higher convergence as the polynomial order increases. Performance accuracy of the Bézier extraction based isogeometric approach is first evidenced by comparing the computed results with the reference solutions, followed by the illustrative examples to further explore the flexural and buckling behavior of FG-CNTRC plates with various reinforcement patterns.

ABSTRACT: The estimation of the critical buckling loads and eigenfrequencies are among the most common problems of mechanical engineering. These parameters are very important measures to avoid the loss of stability of the designed structures. In this work a progressive analytical model of doubly curved shells will be presented and applied to a delaminated spherical shell. The equations are derived using an improved version of the Sanders shell theory and the System of Exact Kinematic Conditions (SEKC). The solution method is based on the Lévy formulation. With this method the governing partial differential equation (PDE) can be reduced to an ordinary differential equation (ODE) with the use of Fourier-series. The resulting set of equations are solved using a variant of the state-space method which is able to solve systems with non-constant system matrix.

ABSTRACT: The wave based method (WBM) is used to analyze the free vibration characteristics of functionally graded material (FGM) cylindrical shell with arbitrary boundary conditions. The motion relationship is described by the first-order shear deformation shell theory (FSDST). The displacement components and transverse rotations are expressed as wave function expansions. In accordance with the dynamic relationship, the final governing equation and global matrix are assembled by incorporating the boundary conditions. The natural frequency of the system is obtained by solving the determinant of the global matrix. By comparing the results with those in the literature, the validity of the proposed method is verified. In addition, the influences of power-law exponents and boundary conditions on natural frequencies are analyzed. The effects of geometric parameters including the ratio of thickness to radius and the ratio of length to the radius on natural frequencies are discussed. The purpose of this paper is to demonstrate the ease of application of the WBM for the free vibration of FGM cylindrical shells with arbitrary boundary conditions. Furthermore, the advantage of the WBM are: (1) the global matrix is easy to construct; (2) different boundary conditions can be conveniently adjusted; (3) it is with high computational efficiency and precision.

ABSTRACT: Thin-walled structures are widely used as strengthened parts or energy absorbers in vehicle bodies. Thus, the collapse behaviors and mechanical properties of thin-walled columns under static and dynamic loads have drawn much attention. During vehicle side crash accidents, the contact parts of vehicles usually deform in the bending collapse mode. Thus, it is significantly important to investigate the collapse behaviors of these parts under the lateral impact. In this study, a new type of Bionic Column with Groove (BCG) was designed, with the inspiration from the lodging resistance features and lightweight of cornstalks. To understand the crashworthiness of BCGs under the lateral impact, we first experimentally established and validated the finite element models of BCGs and Circular Column (CC) under the lateral loading. The simulations agreed well with the experimental tests. Then, the crashworthiness of CC and the BCG were compared, and BCG2-90 outperformed normal CC in specific energy absorption (SEA), bending strength (BS) and crushing force efficiency (CFE). Parametric analyses showed the parameters of the bionic groove significantly affected the crashworthiness of BCG2-90. Finally, a response surface method showed the SEA, BS, and CFE of the optimal design increased by 93.10%, 50.96%, and 15.05% compared with CC respectively. Moreover, the mass reduction relative to CC was 2%. The results from the optimization demonstrate BCG is superior over CC in overall crushing behavior under the lateral impact.

ABSTRACT: The ring on ring (ROR) bending test is an ASTM standard (C1499) for characterizing the equibiaxial flexural strength of ceramics. This simple test protocol induces biaxial flexure by applying an out of plane uniaxial load via a small loading ring, to a plate or disc shaped specimen, simply supported on a larger ring. The main objective of this paper is to apply this test method to analyze the biaxial flexural failure of woven fabric composite plates. Ring on ring bending tests are conducted on square shaped plate specimens of epoxy/carbon plain woven composites, until failure. Experiments reveal interesting similarities and differences when compared to ceramics. First it is seen that while for ceramics the bottom surface fractures under biaxial tension, for woven composites the top surface fractures under biaxial compression. The failure pattern however, is similar to ceramics, and consists of several radial kink bands which initiate near the center and propagate outwards towards the specimen edges. Subsequent numerical stress analysis of the test reveals that the stress state in the region of the plate encompassed by the loading ring is almost exactly equibiaxial. This is primarily because the test method induces pure bending and because the two in-plane principal moduli are equal to each other, and much larger than all the other moduli. This implies near axisymmetry of the stress state despite material orthotropy. This aspect is seen to enable a simple determination of the biaxial flexural strength using the in-situ measured principal strains. It also implies that this biaxial flexural strength could be a good
approximation of the equibiaxial compressive strength for the woven composite, directly measuring which is usually a challenging task. Conditions for the suitability of this test method are explored via further numerical modeling.

ABSTRACT: Thin-walled channel beams are easily punched with circular holes on the web to allow the access for services such as plumbing pipes and electric wires. The presence of the holes can alter the stress distribution in the member and reduce the cross-sectional property. Consequently, it changes its buckling mode. Since perforated cold-formed steel beams are usually placed between main structural frame and corrugated roof, the most common loading case is the uniformly distributed transverse load. Recent work by Chen and Li has given the solution for distortional buckling of channel-, zed- and sigma-sections subject to the uniformly distributed transverse load. This paper is an extension of Chen and Li’s research to explore the distortional buckling behaviour of perforated cold-formed steel beams with holes. The effect of perforations on the critical stress is evaluated. A new model is deduced to predict the critical stress of distortional buckling by reducing the stiffness of the vertical spring. The Rayleigh-Ritz method is used to solve eigenvalue problems. In order to validate the analytical model, finite element analyses have been performed by using ANSYS. When the beam is longer than 3500 mm, the critical stress computed from the analytical model matches well with the critical stress acquired from the finite element analyses.

ABSTRACT: A novel semi-analytical method is presented for buckling analysis of stiffened laminated composite plates with rotationally-restrained edges and under compression and in-plane shear loading. The equivalent model with variable stiffness for stiffened plates is developed, and the Heaviside function is uniquely used to establish the variable stiffness of the stiffened plates along two orthogonal directions. The characteristic equation based on the governing equations of stiffened plates is solved by the Galerkin method. Buckling behavior of stiffened laminated composite plates is obtained and compared with those from both the real geometry and equivalent models by numerical finite element method. Accuracy of the present semi-analytical method is also verified by comparing its predictions with available solutions in literature. A parametric study is conducted to evaluate effects of stiffener geometry, load parameter, and edge rotationally-restrained spring stiffness on buckling behavior of stiffened plates. Finally, practical application of the present semi-analytical method is demonstrated, considering the cross-sectional geometries and material properties of stiffeners, number of stiffeners, and buckling behavior of stiffened plates.

ABSTRACT: This paper describes an investigation of web crippling behaviour of aluminium alloy plain and lipped channels with flanges restrained. A total of 340 data is presented that include 52 test results and 288 numerical results. A series of tests was conducted on plain and lipped channels fabricated by extrusion using
6063-T5 and 6061-T6 heat-treated aluminium alloys under end-two-flange (ETF) and interior-two-flange (ITF) loading conditions. The concentrate loads were applied by means of bearing plates. The flanges of the channels were either bolted (fastened) to one or two bearing plates. A finite element model was developed and verified against the experimental results. Geometric and material non-linearities were included in the finite element model. It was shown that the finite element model closely predicted the web crippling strengths and failure modes of the tested specimens with flanges restrained. Hence, the finite element model was used for an extensive parametric study of cross-section geometries, and the web slenderness value ranged from 24.0 to 207.3. The test results and the web crippling strengths predicted from the finite element analyses were compared with the design strengths obtained using the American, Australian/New Zealand and European specifications for aluminium structures. A unified web crippling equation with new coefficients for aluminium alloy channels with flanges restrained under ETF and ITF loading conditions is proposed in this study. Since two failure modes of web buckling and web yielding were also observed in the aluminium plain and lipped channels with flanges restrained, design rules of web crippling strengths are also proposed by considering the lesser of the web buckling strength and web yield strength.

ABSTRACT: In this paper, an equivalent damage model is proposed to quickly predict the compression after impact (CAI) strength of composite laminates and stiffened panels. Low-velocity impact (LVI) and CAI tests at various energy levels are carried out on laminates. Based on the measured impact damage sizes, the model simplifies the damage area into concentric circles with different stiffness and strength properties by adopting the soft inclusion method. Progressive failure analysis and virtual crack closure technique (VCCT) are used to simulate the intra-laminar and inter-laminar failure of impacted laminates under axial compression in commercial finite element software ABAQUS. The predicted failure modes and CAI strength of laminates are in good agreement with the experiment results from this paper and the literature at various impact energies, which proves the validity of the model. Whilst the numerical model achieves high computational efficiency, the effect of mass scaling on computational efficiency and accuracy is evaluated, which provides a reference for the parameter choice in engineering application. The model is further applied to predict the compressive failure load of the stiffened composite panel with skin bay impact damage as a practical application, showing this modelling approach is also suitable to composite structures.

ABSTRACT: A new type of steel plate shear wall with self-centering energy dissipation braces (SPSW-SCEDB) was developed. Validation tests of the wall plate and the pre-pressed spring self-centering energy dissipation (PS-SCED) braces were conducted and a single-bay, single-story, 1:3-scale SPSW-SCEDB specimen was designed, fabricated, and tested under cyclic loadings. The results demonstrated that the SPSW-SCEDB exhibited a stable flag-shaped hysteretic response with high initial stiffness, appreciable ductility, and excellent self-centering and energy dissipation capabilities due to the synergistic effects of the wall plate and the PS-SCED braces. The proposed theoretical equations of the compressive force of the wall plate, the ultimate lateral load capacity, and the remaining restoring force of the SPSW-SCEDB were verified. The PS-SCED braces reduced the stiffness degradation of the wall plate and improved the lateral force resistance and the stability of the SPSW-SCEDB system. The wall plate provided more energy dissipation than the PS-SCED braces. The remaining restoring force of the PS-SCED braces should be as small as possible to maximize the energy dissipation of the PS-SCED braces while ensuring that it overcomes the compressive force of the wall plate.
ABSTRACT: FRP tube could serve as formwork in new constructions and the square cross-section is convenient for connections. This paper presents an experimental and theoretical study on seawater sea sand concrete (SWSSC)-filled glass/carbon/basalt FRP square hollow section (SHS) stub columns and beams. FRP SHS includes fibres oriented in $\pm 15^\circ$, $\pm 40^\circ$ and $\pm 75^\circ$ with respect to the longitudinal axis so that the hoop and axial strengths are comparable. Both unfilled FRP SHS and SWSSC-filled FRP SHS were tested under axial compressive, three-point or four-point bending loads. SWSSC-filled FRP columns failed by FRP rupture, whereas the failure mode for beams was the crushing of compressive flanges. In this paper, the stress-strain behaviour of columns and moment-strain curves of beams were discussed and compared to the corresponding SWSSC-filled stainless steel (SS) SHS specimens. It was found that existing stress-strain models, which were originally derived for rectangular concrete confined by FRP wrap, cannot precisely capture the stress-strain response of SWSSC-filled FRP columns. Existing models are improved to more accurately predict the ultimate axial strains and stress-strain relationship. A theoretical model is proposed to estimate the moment capacity of SWSSC-filled FRP beams with reasonable accuracy.

ABSTRACT: To improve the resistance of I-girder with concrete-filled tubular flanges and flat-plate web to web shear buckling, corrugated plate is used to replace the conventional flat-plate web to produce a new composite I-girder. To investigate the resistance improvement of the new composite I-girder, i.e., with concrete-filled tubular flanges and corrugated web, experimental tests are currently carried out. Two composite I-girder specimens with flat-plate and corrugated webs, respectively, are designed and tested. Both specimens have a short-span and are subjected to shear action through applying a three-point loading at the mid-span. The test results indicate that no member global buckling occurs for the I-girders both with flat-plate web and with corrugated web attributed to the larger out-of-plane flexural stiffness of the concrete-filled tubular flanges. The composite I-girder with flat-plate web fails due to shear buckling of the web. Because the resistance of the corrugated web to shear buckling is higher, yielding strength, rather than shear buckling of the web, is observed in the composite I-girder with corrugated web. Such different failure modes cause the I-girder specimen with corrugated web to have a much higher load carrying capacity.

ABSTRACT: An analysis on thermal buckling of composite laminated annular sector plates reinforced with the graphene platelets is examined in this research. It is assumed that the graphene platelets fillers are randomly oriented and uniformly distributed in each ply of the composite media. Effective elasticity modulus of the nanocomposite media is extracted utilizing the modified Halpin-Tsai procedure which takes into account the size effects of the graphene fillers. Using the von Kármán type of geometrical nonlinearity and first order shear deformation plate theory, the governing equilibrium equations for the buckling of nanocomposite plates in sector shape under uniform temperature rise are established. Stability equations are obtained using the adjacent equilibrium criterion and solved by means of the generalized differential quadrature method. Numerical examples are given to study the effects of boundary conditions, weight fraction of the graphene platelets, and distribution pattern of the graphene platelets on critical temperature and the fundamental buckled shapes.
Results represent that, with introduction of a small amount of graphene platelets into the isotropic matrix of the composite media, the critical buckling temperature of the plate may be enhanced.

ABSTRACT: Dynamic compression properties of the modified rhombic dodecahedron (RD) lattice structures were investigated by using a Split Hopkinson Pressure Bar (SHPB) system. All the deformation processes were recorded and a digital image correlation (DIC) technique was employed to analyse the strain distribution during the compression process. Experimental results indicated that the modified lattice structure showed better compressive strength, plateau stress and energy absorption when compared with the original one under both quasi-static and dynamic loading conditions. The effect of the shape parameter on the deformation mechanisms of the RD lattice structure was discussed, where three different deformation modes were observed. Finite element analysis was also conducted to simulate the dynamic response of the modified lattice structure. The finite element results are in good agreement with the experimental results. Then, a mode classification map was plotted and discussed based on the numerical results.

ABSTRACT: This paper focuses on the development of beam-column flexural stiffness reduction factor ($\tau_{MN}$) applicable to the in-plane stability design of stainless steel beam-columns and frames with compact cold-formed square and rectangular hollow sections. The proposed $\tau_{MN}$ accounts for the deleterious influence of material non-linearity, residual stresses and member out-of-straightness. The use of a Geometrically Non-linear Analysis (GNA) with the proposed $\tau_{MN}$ eliminates the need for member buckling strength checks and thus, only cross-sectional strength checks are required. The proposed approach, aligned to AISC standards, is aimed at facilitating greater and more efficient use of stainless steel.

Two types of $\tau_{MN}$ are proposed: analytical and approximate. The analytical $\tau_{MN}$ accounts for the deleterious influence of material non-linearity, residual stresses and member out-of-straightness. The use of a Geometrically Non-linear Analysis (GNA) with the proposed $\tau_{MN}$ eliminates the need for member buckling strength checks and thus, only cross-sectional strength checks are required. The proposed approach, aligned to AISC standards, is aimed at facilitating greater and more efficient use of stainless steel.

ABSTRACT: Even though the number of deadly traffic incidents is decreasing, the proportion of motor vehicle crash deaths involving a collision with fixed objects is not. To address this issue, a novel load-bearing energy-absorbing system comprised of brittle blocks with thin-walled cellular structures is presented here, laying the foundation for the assessment of the system's crashworthiness. Six brittle hexagonal cellular structures were subjected to quasi-static and impact tests. The crushing process, force-displacement curves, and a wide range of indicators of crashworthiness were examined. Samples with different levels of crashworthiness were identified and several observations that could guide future crashworthiness design are given. Our findings show that relatively small changes in the design can lead to production of blocks with distinguishable levels of crashworthiness.

ABSTRACT: In this paper, the structural stability of cold-formed stainless steel plain channel columns under axial compression is investigated. Reliable finite element models for channel section columns are first developed and validated against experiments conducted on stainless steel lipped channel specimens. This is followed by a parametric study in which columns made of austenitic, ferritic and duplex stainless steel are assessed. The considered cross-section classes and column lengths cover the entire range of global slenderness. The effects of material and geometrical nonlinearity are considered in the numerical analysis. The numerically generated data are then employed to evaluate the accuracy of the current European and Australian design codes EN 1993-1-4 and AS/NZS 4673 respectively, for predicting the flexural and flexural-torsional column buckling resistance. The results show a necessity to improve the current buckling curve used to predict the flexural buckling resistance of plain channel section columns, currently adopted in EN 1993-1-4, whose use may lead to unsafe predictions, especially for the austenitic grade.

ABSTRACT: This study investigates the ultimate shear strength of unstiffened slender web in prismatic tapered steel beams using newly proposed buckling coefficients raised in the preceding research conducted by the authors [1]. An experimental program is performed using three specimens that are selected to fail in shear without any significant flexural deformations. A three dimensional numerical finite element model is established considering both material and geometrical non-linearities. The finite element model is successfully calibrated to simulate the experimental tests. New procedures are proposed to predict the ultimate shear strength which is validated against the existing experimental results. The developed finite element models are used to expand the validation range of the proposed method to include the practical ranges within the relevant specifications limits.

ABSTRACT: Combining both thermal insulation and structural strength in the core, sandwich pipes (SP) are a promising alternative for conventional single wall pipes in deep-water applications. The ultimate strength of SPs under external pressure has always been a major concern in the design process. An insightful understanding of the collapse pressure and post-buckling behavior of SPs is critical not only for safe application, but also for
optimized design. This paper and its companion paper present a comprehensive study on the collapse pressure of SPs with strain-hardening cementitious composite (SHCC).

Part 1 presents experiments investigating the collapse under external pressure of SPs composed of two steel tubes and the strain-hardening cementitious composite (SHCC) core. The experimental results were employed in correlation studies with the finite element model using the ABAQUS software; good agreement was reached. The proposed numerical model was used in a parametric study for simulating collapse in 6000 different practical configurations. The influence of the geometric parameters and material properties of the SP on its ultimate structural strength under external pressure and post-buckling behavior was systematically analyzed. The results revealed some interesting phenomena not previously reported. For example, assuming frictionless inter-layer conditions, the collapse pressure of an SP with an SHCC core decreases with increasing steel layer thickness. The reasons behind these phenomena were thoroughly discussed and the special behavior of an SP with an SHCC core subjected to external pressure is reported.

The results developed in this paper were utilized in Part 2: A suitable prediction equation, where different equation forms are evaluated and one prediction equation is recommended for the design of an SP with an SHCC core.

**ABSTRACT:** A comprehensive study on the collapse pressure and post-buckling behaviour of a sandwich pipe (SP) with a core of strain-hardening cementitious composite (SHCC) was carried out in Part 1 of two companion papers. The results in the Part 1 paper show that an SP with an SHCC core has a different collapse mechanism from an SP with a polypropylene core. Because of its weak inter-layer adhesion and a relatively hard core, the collapse pressure and the characteristic response of an SP with an SHCC core are more influenced by its strongest layer than by the summed strength of all its layers. Since this behaviour has never been reported before, current prediction equations for the collapse pressure of SP systems cannot capture the special behaviour of an SP with an SHCC core. Therefore, utilizing the available prediction equations for an SP with an SHCC core may lead to unreliable estimates. This Part 2 paper is dedicated to addressing the challenge by proposing a suitable prediction equation.

Based on the extensive simulation results carried out by the numerical model verified by experiments in the Part 1 paper, supervised machine learning techniques were applied to support the regression of different equation forms, which come from three sources: (a) equation forms proposed by previous researchers, (b) equation forms found by the automatic machine learning software EUREQA, and (c) equation forms proposed by us. Further, the performances of the equation forms in predicting accurate results for the collapse pressure were compared. Based on the comparative performances and accuracy, an equation was recommended for the design of SPs under external pressure.

**ABSTRACT:** This paper presents the theoretical part of an experimental study aimed for proposing a novel FRP strengthening technique to strengthen the webs of steel plate girders against breathing fatigue reducing the critical stresses and consequently increasing the life expectancy of the bridge. The proposed technique is economic, easy to install and is also designed for increasing the ultimate capacity of the strengthened specimens by up to 88% while maintaining the typical ductile shear failure of the steel plate girders, which is something not common with other strengthening techniques.

A non-linear finite element model is developed and an extensive parametric study has been performed to propose a new design method for shear buckling of the new composite section including a simplified approach to determine the orthotropic mechanical properties of the proposed FRP section.
ABSTRACT: In this paper, a parameter-free optimization method is presented for optimizing the cross-sectional shape of thin-walled structures, which are often demanded at the early stage in structural designs. The thin-walled cross section is minimized subject to constraints of sectional properties including torsion constant, moment of inertia, and shear center. The optimization problem is formulated as a shape optimization problem, and a boundary integral equation method is employed to solve the problem. The results show that the proposed method is effective and efficient in optimizing the cross-sectional shape of thin-walled structures.
of area, centroid and shear center of the cross section. The problem is formulated as a distributed shape optimization problem, and the shape gradient function is derived using the Lagrange multipliers and the material derivative method. The H1 gradient method, which was proposed as a gradient method in a Hilbert space, is applied to determine the smooth optimal shape. The constraint conditions are satisfied using a linearised constraint equation. The validity of this parameter-free method is verified through several design examples for obtaining the optimal shape of a thin-walled cross section under the constraints of sectional properties.

ABSTRACT: The buckling behavior of the windings of pulsed magnets is analyzed systematically for the first time. The buckling analysis of a pulsed magnet is a complicated problem from the material properties to the geometry and the Lorentz force load. Each layer of the magnet is a composite of a helical conductor winding and a layer of orthotropic fiber. Pulsed magnets are compressed axially and expanded radially simultaneously by the Lorentz force, which is distributed in the whole magnet. The structural properties of the windings are discussed by the linear buckling analysis at first, where the Lorentz force is replaced by axial compressed force applied at the ends of cylinders. Then a more comprehensive analysis that includes all the above factors is presented by the nonlinear buckling model in the ANSYS software. The results show that pulsed magnets have a high risk of buckling. The results also indicate many other valuable conclusions, and even some conclusions will subvert the traditional cognition for the pulsed magnet designing. All these results will promote the pulsed magnet technology, and lay the foundation for the theory of pulsed magnets of ultra-high field.

ABSTRACT: Mimicking anatomical structures like bone can aid in the development of energy absorbing structures that can achieve desirable properties. Accordingly, this study presents the analysis of tubular nested designs inspired by Haversian bone architecture. Based on this design philosophy, a total of 18 nested tube designs with various geometrical configurations were developed. Within each design, the effect of reinforcement walls on the crashworthiness performance is also analysed. A finite element model, validated using quasi-static experimental tests, was used to study the crashworthiness performance and progressive deformation of the nested system. Based on the results, a multi-criteria decision-making method known as Technique of Order Preference by Similarity to Ideal Solution (TOPSIS) was employed to determine the most suitable cross-section that features high energy absorption and low impact force. Consequently, the study identified a nested tube configuration that exhibits superior crashworthiness and high energy absorbing characteristics. The bio-inspired design methodology presented in this study allows the exploitation of variable nested geometries for the development of high-efficiency energy absorbing structures.

ABSTRACT: This paper aims to better understand the influence of longitudinal web stiffeners in the structural behavior of cold-formed steel purlins. A set of specimens with stiffened web and plain web cross-sections were tested on predominantly shear, combined bending and shear, and bending only. Numerical analyses carried out in CUFSM and ANSYS investigated the buckling behavior of the sections, allowing the determination of elastic
critical stresses and the calculation of the resistance for the tested specimens by Direct Strength Method (DSM). Numerical results showed that the intermediate web stiffeners improve the buckling strength in loading cases of pure bending and pure shear. Experimental and numerical data were used to evaluate the interaction between bending moment and shear force, and showed that the circular interaction diagram was conservative and the results were closer to the trilinear interaction diagram. The comparison between experimental data and DSM predictions demonstrated that DSM provides accurate estimates for shear and flexural strengths of purlins with stiffened web cross-section.

ABSTRACT: Thin-walled conical shells are extensively used in a variety of engineering applications. The major concern in the design of these thin-walled structures is the buckling failure. One potential strategy for improving the buckling stability performance of conical shells may be the employment of carbon fiber reinforced polymer (CFRP) composite materials for reinforcement purposes. On this basis, a detailed numerical study is conducted on the buckling performance of CFRP-strengthened conical shells under uniform external pressure and reported in this paper. To this end, numerous conical shell models with different slenderness ratios, strengthened circumferentially and meridionally at different locations and directions using CFRP stripes with 0, 45, and 90 fiber orientations are investigated through linear and nonlinear buckling analyses using ABAQUS finite element software. The results and findings of this research are indicative of effectiveness of the reinforcing CFRP laminates in increasing the stiffness and buckling strength of such structures. Specifically, the circumferential reinforcement of the bottom third region using [45/90] reinforcing CFRP stripes is found to be the superior approach for improving the buckling stability performance of conical shells.

ABSTRACT: The ballistic resistance and energy absorption characteristics of the thin hemispherical shells were evaluated against ogive and blunt nosed projectile impact with varying span and configuration of the shell. The span diameter of the 1100-H12 aluminium shell was varied as 68, 100, 150 and 200 mm whereas the configuration of the shell was varied as monolithic and double layered (0.5/0.5, 0.33/0.67 and 0.67/0.33) which was hit at the crown by 19 mm diameter, 50.8 mm length and 52.5 g mass projectile. Three dimensional numerical simulations were carried out through commercially available finite element code ABAQUS. The accuracy of the numerical model was validated by comparing the numerical result of monolithic shell with experimental result conducted through the pressure gun. Numerical simulation result were further employed to extract the total energy absorption in plastic deformation by computing the strain energy in stretching in polar, radial, elevation and shear directions of the shell by using a user defined programme written in python. The influence of projectile nose shape, incidence velocity of the projectile and configuration of the hemispherical shell on the mechanics of failure, ballistic resistance, ballistic limit and energy dissipation characteristics were studied. The double layer hemispherical target showed better performance against ogive nosed projectile however opposite behaviour was observed against blunt nosed projectile.

ABSTRACT: Ring-stiffened cylindrical shells are often used in offshore and submergible structures, it is important for the structural safety to estimate the buckling strength of those under extremely high water pressure. Although the buckling strength can be accurately calculated using the finite element analysis (FEA), the estimation by more easy way is required at an initial stage of the structural design. This paper proposes two formulas for the local shell and stiffener-tripping buckling strength of the ring-stiffened cylindrical shells under external pressure. One can estimate the tripping buckling strength only and is derived assuming the tripping buckling as buckling of only the flange-beam supported by springs and considering effects of the cylindrical shape and torsional stiffness which are not included in a conventional formula. The other can estimate both the shell and tripping buckling strength and is considered interaction of buckling deflection between a cylindrical shell and ring-stiffeners and influence of stresses acting on the web which are not included in conventional formulas. Based on the principle of minimum potential energy, the formula is derived using the functions to express the buckling deformation in the cylindrical shell and ring-stiffeners. The buckling strength estimated by the two proposed formulas is compared with that by existing conventional formulas and the finite element analysis, and this study discusses the influence of new considerations on the shell and tripping buckling strength. From the results, it is found that the second formula can deal with any buckling mode and has greatly high accuracy compared with other conventional formulas.

ABSTRACT: In this paper, the low-velocity impact of metal foam-filled circular tubes are investigated. Based on the quasi-static method, an analytical model is developed to predict the plastic behaviors of the fully clamped metal foam-filled circular tube under the low-velocity impact. Effects of local denting and filled foam strength on the overall bending of the foam-filled tube are considered. Finite element analysis are conducted to study the dynamic response of clamped metal foam-filled circular tube. Good agreement is achieved between the analytical and numerical results. The effect of the filled foam on the dynamic response of the foam-filled tube is discussed. It is demonstrated that the present analytical model is valid to predict the low-velocity of foam-filled circular tubes.

ABSTRACT: Currently, finite element (FE) model is built for analyzing the shear performance of I-girder with concrete-filled tubular flanges (CFTFs) and corrugated web (CW). The accuracy of the built FE model is verified through comparison with experimental results. The failure mechanism of the composite I-girder is investigated from the FE simulations. Based on such failure mechanism, theoretical analyses are carried out to deduce equations for predicting the flexural strength of the CFTFs and the shear yielding strength of the CW. The presented equations are then evaluated, to ensure their accuracy and reliability, through comparisons with experimental results and a parametric study of 30 FE models. From the presented equations, it is found that the shear stress still distributes uniformly along the web height and the bending moment is completely sustained by the CFTFs. However, it is not suitable to assume that all of the shear force is sustained by the corrugated web because the CFTFs also sustain about 12% of the shear force.

ABSTRACT: This paper reports the latest results of an ongoing investigation on the accuracy of the codified Direct Strength Method (DSM) global strength curve in predicting the ultimate strength of cold-formed steel columns failing in flexural-torsional modes. The first part of the paper is devoted exclusively to fixed-ended columns and continues recent work by the authors [1, 2] on the improvement of the flexural-torsional failure load estimation, in the moderate or high slenderness ranges - it is shown that the use of a novel set of strength curves, dependent on a cross-section normalised geometric parameter (involving the area, major and minor moments of inertia, and warping constant), leads to excellent failure load predictions, eliminating the large scatter stemming from the codified design curve and improving the DSM-based design approach proposed in [2]. The second part of the paper aims at extending the investigation to columns with other support conditions, namely three types of pinned supports, all fixed with respect to torsion and having warping prevented; end cross-sections attached to rigid plates resting on spherical or cylindrical hinges (i.e., pinned with respect to major and/or minor-axis flexure). Initially, a parametric study is performed, aimed at gathering failure loads concerning columns (i) with the cross-section shapes considered earlier (plain channels, unstiffened and stiffened lipped channels, return lipped channels, hat-sections and rack-sections), (ii) with various geometries (cross-section dimensions and lengths) and (iii) covering a wide slenderness range. These failure load data are then used to assess the quality of their estimates provided by the codified global DSM strength curve and by the strength curve set developed for fixed-ended columns. It is found that neither of them yields consistently good failure load estimates, which prompts (i) an in-depth comparative study on the elastic post-buckling strength of fixed-ended and pin-ended columns, and (ii) the proposal of modifications that lead to an efficient failure load prediction for the pin-ended columns - although the failure load set obtained in this work is necessarily limited, the fact that their predictions by the proposed DSM global design curves (i) exhibit very high quality and (ii) clearly outperform those yielded by the current design curve provides strong encouragement to search for further experimental and numerical validation.

ABSTRACT: This study presents the functionally graded viscoelastic model for calculating the wave propagation through a plate made of polymeric foam. The polymeric foam is a type of material that has both functionally graded and viscoelastic phases. The shear moduli and complex Young’s of polymeric foam are frequency dependent. Additionally, elasticity modulus and mass density vary with the change of distribution function through the plate thickness. The first-order shear deformation theory has been applied for deriving the governing equations. Moreover, Zener mathematical model has been used for the description of the viscoelastic
behavior of plate made of polymeric foam. This structure is excited by a plane wave with two elevation and azimuth incident angles. Due to the lack of researches in the vibroacoustic field of these materials, the results have been compared with those from other researchers for an isotropic material. Finally, the effects of various physical, geometrical, and environmental parameters on the wave propagation of polymeric foam plates have been analyzed. It has been demonstrated that sound transmission loss increases by enhancing material constant and decreasing the power-law index. Moreover, the obtained results show that the sound transmission loss for the functionally graded viscoelastic is enhanced in comparison with elastic, viscoelastic, and functionally graded material with lower masses.

“A simplified-but-general nonlinear thin-walled beam finite element model with independent interpolated axial displacement”, Article 106467, Thin-Walled Structures, Vol. 148, March 2020,
https://doi.org/10.1016/j.tws.2019.106467
ABSTRACT: This paper presents a study performed on the simplified thin-walled beam finite element model that takes into account the effects of shear deformation and higher-order axial displacement. Without using the torsion-related warping function derived from classical theories, the axial displacement field over the cross-section is constructed by using independent Lagrange interpolation polynomials. Then, the effect of shear stress distribution can be reasonably included and the beam model is dedicated to thin-walled members with arbitrary cross-section. The expressions of the Green-Lagrange strain components are derived. The element elastic stiffness matrix and geometrical stiffness matrix are obtained to perform static and buckling analyses. Numerical examples are employed to demonstrate the effectiveness of the proposed model and discuss the probable accuracy-loss from different deformation assumptions and nonlinear strain definitions. As revealed by the results, the transverse shear deformation and higher-order axial displacement could exert significant effects on solution accuracy for static and buckling analyses under the circumstances of small slenderness and unsymmetrical cross-section. In addition, the nonlinear strain terms related to torsion and quadratic terms of the transverse shear deformation are found to be crucial to stability analysis, for which they ought to be included in a simplified strain definition.

“Distortional strength of end-bolted CFS lipped channel columns: Experimental investigation, numerical simulations and DSM design”, Article 106469, Thin-Walled Structures, Vol. 148, March 2020,
https://doi.org/10.1016/j.tws.2019.106469
ABSTRACT: This paper reports the results of an experimental investigation and numerical simulations concerning the influence of bolted end support conditions on the failure loads of cold-formed steel lipped channel columns buckling and failing in distortional modes, as well as on their prediction by means of the Direct Strength Method (DSM). The end supports consist of pairs of cylindrical high-strength bolts with hexagonal heads and nuts, which are inserted in standard-sized holes located at the intersections of the cross-section flanges with the minor principal centroidal axis (parallel to the web). After selecting the column geometries (cross-section dimensions and lengths) and yield stresses, the test set-up and procedure are described in detail, and the experimental results obtained are presented and discussed. Such results consist of initial imperfection measurements, equilibrium paths relating the applied load to key column displacements, deformed configurations (including the collapse mode) and failure loads. Next, those same experimental results are used to validate a previously developed shell finite model, which is subsequently employed to obtain additional numerical failure load data concerning the end-bolted columns under scrutiny. Then, attention is turned to assessing the merits of the available DSM column distortional design curves. Because it is concluded that these design curves clearly overestimate the failure load data obtained, new/modified strength curves are preliminarily proposed and shown to considerably improve the prediction quality (safety and reliability) of the
end-bolted column failure loads, thus providing motivation and encouragement to continue the search for an efficient DSM-based design approach for end-bolted columns failing in distortional modes.

ABSTRACT: Previous research has revealed shortcomings in the current Eurocode 3 (EC3) provisions for the design of semi-compact (Class 3) cross-sections. These shortcomings arise primarily from the lack of utilisation of partial plastification in bending, leading to a step in the design resistance function at the boundary between Class 2 and 3 cross-sections and an underestimation of the available capacity. This affects the accuracy of resistance predictions in bending and under combined loading, and applies at both cross-sectional and member level. To address this issue, the use of an elasto-plastic section modulus, which lies between the plastic and elastic section moduli, has been proposed and employed in the design of semi-compact I- and box sections. The aim of the present study is to develop new cross-section and member buckling design rules incorporating the elasto-plastic section modulus for semi-compact circular hollow sections (CHS), and to assess their accuracy against existing experimental and freshly generated numerical data. Firstly, an experimental database, consisting of previous cross-section and member buckling test results on steel CHS, was established. A comprehensive numerical simulation programme was subsequently carried out; in this programme, finite element (FE) models were developed, validated and used for parametric studies, where over 600 numerical structural performance data on semi-compact CHS were generated. New sets of cross-section and member buckling design expressions featuring elasto-plastic section properties were then proposed and assessed against the test and numerical data. The proposals were shown to offer improved accuracy and design efficiency over the elastic EC3 methods. The reliability of the proposed elasto-plastic design rules was then confirmed through statistical analyses in accordance with EN 1990, demonstrating their suitability for inclusion into the next revision of EN 1993-1-1.

ABSTRACT: This paper proposes a strain gradient differential quadrature finite element method to analyze the size-dependent static and dynamic behaviour of Reddy-type micro-beams. This element has 6 of freedom per node and avoids the exploitation of shape functions. A sixth-order differential quadrature-based geometric mapping scheme is constructed to realize the higher-order continuity requirements of kinematic variables. And then, it is combined with the minimum total potential energy principle to derive the motion equation of a generic element. Afterwards, several numerical examples are provided to establish the validity of the developed element. Finally, we utilize this method to analyze the static bending, free vibration, and linear buckling characteristics of uniform and stepped micro-beams. Numerical results show that the current element has prominent convergence and adaptability advantages over the classical shape function-based element. Besides, the size-dependence of vibration and critical buckling mode shapes of micro-beams is demonstrated in the graphical form for the first time.

ABSTRACT: To provide reference solutions and results for structural and material design, nonlinear transient responses of porous functionally graded plate (PFGM) in hygro-thermo-mechanical environments are studied. Two different porous distributions through the thickness are considered. The material properties such as Young's modulus, Poisson's ratio and thermal conductivity are computed by a modified power law. The hygro-thermal effects are considered as nonlinear through the thickness of the plate. The geometrically nonlinear transient behaviors are expressed by adopting the von Kármán relations and solved by Newmark time integration scheme. Based on a combination between the third-order shear deformation theory (TSDT) and isogeometric analysis (IGA), discretize governing equations are approximated. These approaches achieve naturally any desired degree of continuity of basis functions, so that they are easy to fulfill the C-continuity requirement of the plate model. The formulations take into account the transverse shear deformation and account for the material properties at elevated moisture concentrations and temperature. The effects played by the moisture concentration, temperature rise, porous volume fraction, boundary conditions and thickness-to-length ratio are performed and results illustrate interesting dynamic phenomenon for PFGM in hygro-thermo-mechanical environments. With obtained results, the nonlinear characteristics of the proposed structure with porosities are based on physical parameters.

ABSTRACT: The cylindrical shell is a basic structure in transportation of dangerous goods, hydrogen storage, public safety, aerospace industries, nuclear and power engineering. The dynamic burst pressure of cylindrical shells is crucial to personal safety, environmental pollution and property damage. Based on average shear stress yield (ASSY) criterion, a novel equation is developed to predict the dynamic burst pressure of cylindrical shells. The ASSY criterion is a weighted average of the maximum shear stress and octahedral shear stress. Firstly, the non-uniform impact load is reduced to a parabolic load acting on the inner wall of cylindrical shells. The width of load is the same as the outer diameter of the cylindrical shell. And then, ASSY criterion is adopted to predict the dynamic burst pressure of cylindrical shells for the first time. In the end, the accuracy of our method is validated by comparing with the finite element method (FEM) under different pulse duration. The results indicate that our method can accurately predict the dynamic burst pressure of cylindrical shells under a non-uniform impact load. In addition, the ASSY criterion can be extended to solving dynamic problems with a high precision. Finally, our method can be used as a benchmark for approximate or numerical solutions. It is beneficial to assess the safety and integrity of cylindrical shells under a non-uniform impact load.

ABSTRACT: The present paper describes an in-depth experimental and numerical investigation into the flexural responses and strengths of press-braked S690 high strength steel channel section beams bent about the minor principal axes in both the ‘u’ and ‘n’ orientations. The experimental study was performed on eight press-braked channel sections, and comprised twenty-four material flat and corner coupon tests, initial local geometric imperfection measurements, and twelve beam tests in the four-point bending configuration. This was followed by a complementary numerical modelling programme, where finite element models were firstly developed and validated against the test results and afterwards adopted for performing parametric studies to obtain an additional numerical data bank over a wide variety of cross-section geometric sizes. The acquired test and numerical data were then employed to evaluate the applicability of the Eurocode slenderness limits for welded and hot-rolled internal webs (in compression) and outstand flanges (in stress gradients) to their press-braked
counterparts, revealing that the Eurocode slenderness limits can be safely extended to cover the classifications of plate elements and cross-sections of press-braked S690 high strength steel channel section beams. Evaluation of the accuracy of the cross-section flexural strengths predicted from various design codes established in Europe, North America and Australia/New Zealand was also made, based on the test and numerical data. The results of the quantitative evaluation generally revealed that (i) all the examined design codes lead to overall conservative and scattered predicted cross-section flexural strengths for press-braked S690 high strength steel channel section beams, and (ii) the European code results in more precise design flexural strengths for beams with relatively stocky channel sections, but less accurate strength predictions for beams with relatively slender channel sections, compared to the North American and Australian/New Zealand standards.

ABSTRACT: This paper reports a study on the large amplitude nonlinear vibration of carbon nanotube-reinforced composite (CNTRC) laminated plates with negative Poisson's ratios in thermal environments. The constituent materials of CNTRCs are temperature-dependent and the plate is functionally graded (FG) in a piece-wise pattern in the thickness direction of plate. An extended Voigt (rule of mixture) model is adopted to quantify the CNTRC material properties of the laminated plate. The governing motion equations for the large amplitude vibration of FG-CNTRC laminated plates are based on the Reddy's third order shear deformation theory and the von Kármán-type kinematic nonlinearity framework, and the thermal effects and the reaction from elastic foundation are taken into account. The nonlinear solution of the motion equation can be obtained by applying a two-step perturbation approach. The effects of material property gradient, the temperature variation, stacking sequence as well as the foundation stiffness on the vibration characteristics of CNTRC laminated plates are examined and discussed in depth through a parametric study. The results show that negative Poisson's ratio has a significant effect on the linear and nonlinear vibration characteristics of CNTRC laminated plates.

ABSTRACT: Foldcores have been regarded as a promising alternative to the conventional honeycomb core in lightweight sandwich structures, especially in the aerospace sector. Current research on foldcores is mainly focused on the Miura pattern. However, the Miura-based foldcores provide only edge-based bonding interfaces to the skins, which may cause a weak core-skin bonding strength. In this paper, foldcores based on the generalized Resch patterns are researched, which can provide face-based bonding interfaces. The content of the paper is threefold. First, a generic geometric design method to generate the geometries of foldcores based on the generalized Resch patterns is proposed. Second, the finite element procedures to model foldcores under quasi-static compression and shear are developed and validated through experimental results. Third, a parametric study on the quasi-static mechanical properties of foldcores of different types and with different geometries is performed. It is shown that foldcores based on the hexagonal pattern have the highest peak stress and energy absorption capacity among the three types of generalized Resch patterns, and the multi-layered foldcore in general outperforms the single-layered counterpart. When compared with the Miura-based foldcores, the generalized Resch-based foldcores assume better performance in the energy absorption capacity.

ABSTRACT: The objective of this paper is to develop a systematical Direct Strength Method (DSM) design formulation with a design criterion that can properly identify the occurrence of the Local and Distortional (L/D) buckling interaction for cold-formed steel compressive members and thus predict the strength. Column tests provided clear evidence of the L/D interaction and revealed the difference between the L-D and D-L interactions depending on which one buckles first. By collecting all the experimental data of cold-formed steel columns related to the L/D interaction, the current DSM predictions are first evaluated. Then, a DSM-based interaction formulation with design criterion by replacing the pure mode prediction with the interaction prediction based on the identification of the design criterion is proposed. The accuracy of the proposed method is evaluated from all the collected data experiencing the L/D interaction. Moreover, the effectiveness of the design criterion in identifying the interactive failure is also highlighted.

ABSTRACT: The behavior of concrete filled steel tubular (CFST) elements with different types of stiffening measures has been widely investigated during the past two decades through experimental, analytical, and numerical approaches. The previous studies highlighted the importance of the presence of internal and external stiffeners to enhance the structural performance of CFST elements under different loading conditions. In this paper, a systematic methodology is proposed in order to rigorously review the current knowledge in literature about stiffened CFSTs. The reviewed studies include tests of static axial compression, pure bending and combined of static loading actions as well as the cyclic behavior and the fire resistance. A coherent taxonomy regarding the research of stiffened CFSTs is proposed based on the loading conditions besides their cross-sectional shape and type of stiffeners. The study also presents a number of practical applications of stiffened CFSTs in different engineering projects. Finally, concluding remarks, current research gap and future research directions on stiffened CFST are provided and discussed.

ABSTRACT: Understanding the mechanical response of structures such as plates and thin-walled extrusions subjected to cutting and tearing by hardened wedges (blades) is of great interest to scientists and engineers. This complex problem arises in a plethora of disciplines, including but not limited to the broad spectrums of manufacturing, construction and engineering design. Furthermore, studying this topic is a comprehensive endeavor which incorporates advanced concepts within stress analysis and materials science. Despite these challenges, a multitude of advancements were achieved through extensive physical testing, followed by the subsequent development of theoretical explanations and modeling efforts. This paper reviews the major contributions in recent decades towards understanding cutting-induced plastic deformation through experimental, analytical and numerical modeling techniques. The plate tearing problem was historically of interest to the ocean engineering community as an approximation for ship grounding incidents. More recently, the potential for cutting to serve as a means of energy dissipation for enhanced vehicular safety was identified due to the characteristic near-constant force response. Experimental studies were conducted from quasi-static to high rate blast loading conditions (V > 100 m/s). Numerical modeling with Eulerian mechanics and meshfree element formulations were identified as the most accurate techniques, although these schemes are computationally expensive. Analytical solutions are highly sought after since they provide valuable information almost instantaneously. Early modeling efforts yielded purely empirical relationships with gradual
improvement, followed by the development of fully analytical formulations which rely upon approximations of the strain fields in combination with the principle of virtual power to obtain resultant forces.

ABSTRACT: The existing literature concerning the axial performance of concrete-filled double skin tubular (CFDST) columns has been reviewed in this paper. The models in the literature for predicting the behavior of steel materials and confined concrete are summarized, and their effects of the results of finite element analysis are discussed. The applicability and accuracy of four design guidelines to predict the ultimate axial strength of CFDST columns have been assessed through this review by using an expanded database of published compression tests. Code limits in cross-sectional slenderness and material strength are reviewed. The impacts of different structural parameters on the axial behavior are reviewed and discussed. The discussion results indicate that material properties and dimensions have significant effects on the axial performance of CFDST columns. The European and Australian codes give the most reliable predictions, while American design codes give conservative predictions. Finally, recommendations for future studies are provided.

Lulu Wei, Xuan Zhao, Qiang Yu and Guohua Zhu (School of Automobile, Chang'an University, Xi'an, 710064, China), “A novel star auxetic honeycomb with enhanced in-plane crushing strength”, Article 106623, Thin-Walled Structures, Vol. 149, April 2020, https://doi.org/10.1016/j.tws.2020.106623

ABSTRACT: Auxetic honeycombs exhibit low weight, shear stiffness, and excellent energy absorption capacity and thus have great potential for achieving the requirements of crashworthiness and lightweight in automotive fields. This work presents a novel auxetic structure called the star-triangular honeycomb (STH), in which the horizontal and vertical ligaments of the star honeycombs (SH) are replaced with triangular structures. The dynamic crushing behaviors of the STH under three different crushing velocities were investigated using 1D shock theory. The results show that the STH has a more obvious negative Poisson’s ratio effect than the SH and that transverse contraction mainly occurs in the first plateau stage. Theoretical models were deduced based on the collapse mechanism of the typical unit revealed by numerical simulation for STH crushing strength prediction. The theoretical predictions agreed well with the simulation results, and two different plateau stresses appeared under low-velocity crushing. In addition, the influences of the STH geometric parameters and crushing velocity on the energy-absorbing capacity and densification strain were systematically explored. The parameter analysis indicated that the effects of the cell-wall thickness and incline angle on the dynamic response and energy absorption capacity of the STH under low-and medium-velocity crushing are more significant than those under high-velocity crushing. Moreover, the STH showed better energy absorption capacity than the SH. Thus, this design is expected to provide a novel means of improving the mechanical properties of honeycombs.

ABSTRACT: Thin-walled tubes have been mostly used in passive vehicle safety systems as crash energy absorber. With the use of additive manufacturing technology, it is possible to produce novel filler materials to further enhance the crashworthiness performance of thin-walled tubes. In this study, optimal designs of novel lattice structure filled square thin-walled tubes are investigated under axial impact loading by using a compromise programming based multi-objective crashworthiness optimization procedure. Types of filler lattice structures (i.e., body-centered cubic, BCC and body-centered cubic with vertical strut, BCC-Z), diameter of lattice member, number of lattice unit cells and tube thickness are considered as design parameters, and the optimum values of these design parameters are sought for minimizing the peak crash force (PCF) and maximizing the specific energy absorption (SEA) values. The validated finite element models are utilized in order to construct the sample design space and carrying out results verification; an artificial neural network is
employed for predicting values of the objective functions; the weighted superposition attraction algorithm is used to generate design alternatives and searching for their optimal combination. The compromise programming approach is used to combine multi-objectives and to produce various optimal design alternatives. The optimization results showed that the proposed approach is able to provide good solutions with high accuracy and proper selection of design parameters can effectively enhance the crashworthiness performance of the lattice structure filled thin-walled tubes. The optimum results revealed that BCC hybrid designs have generally superior crashworthiness performance compared to that of their BCC-Z counterparts for the same compromise solutions. In particular, the PCF value of the optimized BCC-Z hybrid structures is up to 44% higher than that of BCC hybrid structures while these structures have similar energy absorption performances. The compromise solutions also show that the SEA of BCC and BCC-Z hybrid structures increases respectively by 29% and 51% depending on the selected weight factors for the design objectives.

ABSTRACT: The post-fire performance of concrete-filled stainless steel tubular (CFSSST) columns subjected to an entire loading–fire history, including four characteristic phases: (i) ambient temperature loading, (ii) heating, (iii) cooling with constant external loads, and (iv) post-fire loading, is investigated in this paper. Sequentially coupled thermal-stress analyses are performed using ABAQUS to establish the temperature field and structural response of CFSSST columns. To improve the precision of the finite element analysis (FEA) models, the influence of moisture on the thermal conductivity and specific heat of the concrete in the heating and cooling phases is considered by using subroutines. Existing fire and post-fire test data on CFSSST columns are used to validate the FEA modelling. Comparisons between FEA and test results indicate that the accuracy of the model is acceptable; the FEA model is then extended to simulate CFSSST columns subjected to the four characteristic phases. The behaviour of the CFSSST columns during the four characteristic phases is explained by analysis of the temperature distribution, load versus axial deformation relations, failure modes and internal force redistribution. The excellent post-fire performance of CFSSST columns is examined in comparison with traditional concrete-filled stainless steel tubular (CFST) columns with the same total cross-sectional area. The residual strength index is studied with respect to a series of parametric analyses. It is found that the residual strength of CFSSST columns is higher than that of CFST columns after the same fire exposure, and that the diameter of the stainless steel tube, slenderness, heating time ratio and load ratio have a significant influence on the residual strength index.

ABSTRACT: Open holes and cutouts have been widely used in composite structures for various engineering purposes. However, perforation could largely alter the structural responses and crasching behavior, thereby creating significant change in composite design. This study carried out a parametric study and design optimization on the perforation parameters for the perforated carbon fiber reinforced plastic (CFRP) square tubes to improve the structural crashworthiness. First, a finite element model was established for perforated square tube through experimental validation. Second, the support vector regression (SVR) surrogate models of the crashworthiness indices were established with respect to the perforation design variables following a
parametric study. It was found that the radius of the hole had the most significant effect on crashworthiness performance of the CFRP tube, followed by the height-to-length ratio and the offset-to-width ratio of the hole. Finally, the multiobjective optimization was performed to optimize the perforated parameters by integrating the surrogate modeling technique and multiobjective grey wolf optimizer (MOGWO). The optimal design enabled to enhance 100.47% in the specific energy absorption (SEA) (specifically from 29.61 J/g to 59.36 J/g) only with a minor sacrifice of 4.62% in the first peak load (Fmax) (from 81.22 kN to 84.97 kN).

Farhad Alinaghizadeh and Mahmoud Shariati (Department of Mechanical Engineering, Faculty of Engineering, Ferdowsi University of Mashhad, Mashhad, Iran), “Nonlinear analysis of size-dependent annular sector and rectangular microplates under transverse loading and resting on foundations based on the modified couple stress theory”, Article 106583, Thin-Walled Structures, Vol. 149, April 2020, https://doi.org/10.1016/j.tws.2019.106583

ABSTRACT: The nonlinear behavior of annular sector microplates remains poorly understood. In this study, a non-classical model for nonlinear bending analysis of annular sector microplates under transverse mechanical loading is developed based on the modified couple stress theory and the first-order shear deformation theory with von Karman nonlinearity. The model captures the size effect by a material length scale parameter. Using the principle of minimum total potential energy, the equilibrium equations and boundary conditions are obtained. The equilibrium equations are discretized according to the generalized differential quadrature method and are solved using the Newton's technique. By a proper change in the geometric parameters of annular sector plates, the results are extended to nonlinear analysis of square microplates under transverse loading. It is assumed that the microplates are resting on the nonlinear elastic foundations. The present results are verified by comparison with existing results in the literature. The effects of nonlinearity, length scale parameter, foundation parameters and geometric parameters on deflections of annular sector and square microplates subjected to distributed transverse loading are studied.

ABSTRACT: The objective of this study was to investigate the influence of eccentric compressive load on the buckling, post-buckling and load-carrying capacity of thin-walled top-hat cross-section composite columns. The CFRP columns were manufactured by the autoclave technique. The scope of the study involved performing experimental tests on real structures as well as numerical calculations by the finite element method. The experimental tests were conducted in the full range of loading, until the structure's failure. Post-buckling equilibrium paths and acoustic emission signals were measured in order to determine actual condition of the composite material. Nonlinear FEM calculations were made by the progressive damage criterion, in which the damage initiation of the composite material was estimated based on Hashin's theory, whereas damage evolution was described by the energy criterion. The numerical simulations were performed using the commercial software ABAQUS®. The numerical results were in good agreement with the experimental results obtained for real structures. The results demonstrated a significant influence of eccentric compressive load on the buckling and post-buckling characteristics of the tested structures.

ABSTRACT: In this paper, the lateral indentation of a newly proposed reinforced braided tube with tunable stiffness, which takes a braided tube as skeleton and is sealed by thin membranes, has been studied experimentally and numerically. It is found out that the radial stiffness could be increased by 290% compared
with that of a stand-alone braided tube, through adjusting the negative pressure between the braided skeleton and the membranes. During deformation, the fibers in the reinforced tube are longitudinally restricted by friction, which increases the stiffness of the braided skeleton. In addition, friction dissipation due to sliding between fibers and membranes also contributes substantially to the load carrying capability of the reinforced tube, leading to a much stiffer structure than the summation of the constituents. A parametric analysis has also been conducted, from which the effects of the design parameters are obtained.

ABSTRACT: This paper is focused on the identification of the in-plane elastic constants of a new design of auxetic (negative Poisson's ratio) honeycomb configuration with curved cell walls by using analytical and numerical homogenization techniques. The sensitivity of the elastic constants is determined against the various cell geometry parameters. Good agreement between the analytical and numerical simulations is observed. We show that the specific curved wall honeycomb configuration proposed in this paper possesses a high in-plane shear compliance, tailored anisotropy and the possibility of inducing a negative Poisson's ratio behaviour in baseline honeycomb configurations that would have otherwise positive in-plane Poisson's ratios.

Shubin Wang, Weiguo Li, Yong Tao, Xin Zhang, Xuyao Zhang, Ying Li, Yong Deng, Zheng Shen, Xi Zhang, Jiasen Xu, Liming Chen and Daining Fang (All except the last author are from: College of Aerospace Engineering, Chongqing University, Chongqing, 400044, China), “Investigation on the temperature dependent out-of-plane quasi-static compressive behavior of metallic honeycombs”, Article 106625, Thin-Walled Structures, Vol. 149, April 2020, https://doi.org/10.1016/j.tws.2020.106625

ABSTRACT: This study investigates the effect of temperature on the out-of-plane quasi-static compressive behavior of metallic honeycombs by numerical and theoretical methods. Adopting a temperature dependent elastic-perfectly plastic constitutive relation, the temperature dependent out-of-plane quasi-static compressive mechanical performance of Al5052 honeycomb is studied with the finite element method. The results show that the plateau stress, peak stress and specific energy absorption (SEA) of Al5052 honeycomb decrease gradually with increasing temperature, while the crush load efficiency (CLE) and deformation pattern are temperature insensitive. Then, based on the numerical results in this study and super folding element theory, the temperature dependent theoretical models without fitting parameters for the plateau stress and SEA of metallic honeycombs are developed, respectively. These theoretical models are successfully verified against numerical simulations and experiments. Based on these theoretical models, the effects of parent material properties on the plateau stress and SEA at different temperatures are discussed. The results in this study provide useful guidelines in optimizing the choice of parent materials to fabricate metallic honeycombs with better energy absorption efficiency at different temperatures.

ABSTRACT: Thin-walled structures have been widely used as energy-absorbing components, which can be probably subjected to multiple loading conditions in real life, such as axial crushing and lateral bending. Most of the existing literature solely focuses on the pure axial crushing or lateral bending. In this paper, a novel tailored-property multi-cell tubular structure is proposed, where the material's ultimate strength at the corner
region is increased to accommodate both the axial crushing and lateral bending conditions. Finite element (FE) models were developed and validated through experimental results. The FE models were used to investigate the crashworthiness performances of the tailored-property multi-cell tubes under axial crushing and lateral bending. Under both axial crushing and lateral bending, it was found that the tailored-property multi-cell tubes exhibited noticeable advantages over the corresponding traditional tubes. The tailoring ratio and thickness had a significant influence on the crashworthiness performance of the tailored-property multi-cell tubes. Moreover, the well-designed tailored-property multi-cell tubes could exhibit the progressive deformation mode under axial crushing. Furthermore, a theoretical model for the tailored-property multi-cell tubes under axial crushing was developed based on the Superfolding Element (SFE) Method. The results showed that the theoretical solutions were in good agreement with the finite element analysis results. The findings of this paper have the potential for energy absorption applications under different loading conditions.

ABSTRACT: The structural fire response of hot-rolled steel square and rectangular hollow sections (SHS and RHS) under combined compression and bending is investigated in this study through finite element (FE) modelling. The developed FE models were firstly validated against available test results on hot-rolled steel SHS/RHS subjected to combined compression and bending at elevated temperatures. Upon validation, an extensive parametric study was then carried out to examine the resistance of hot-rolled steel SHS/RHS under combined loading at elevated temperatures, covering a wide range of cross-section slendernesses, cross-section aspect ratios, combinations of loading and temperatures up to 800 °C. The numerical data, together with the experimental results, were compared with the strength predictions according to the current structural fire design rules in the European Standard EN 1993-1-2 (2002) and American Specification AISC 360–16 (2016) for hot-rolled steel SHS/RHS under combined loading. The comparisons generally indicated significant disparities in the prediction of resistance of hot-rolled steel SHS/RHS under combined loading at elevated temperatures, owing principally to inaccurate predictions of the end points of the design interaction curves. The deformation-based continuous strength method (CSM) has been shown to provide accurate strength predictions for these end points i.e. the resistances of hot-rolled steel SHS/RHS stub columns and beams at elevated temperatures. In this study, proposals are presented to extend the scope of the CSM to the structural fire design of hot-rolled steel SHS/RHS under combined compression and bending. The CSM proposals are shown to offer improved accuracy and reliability over current design methods and are therefore recommended for incorporation into future revisions of international structural fire design codes.

were tested with no holes in the webs. Three different section thicknesses and square hole sizes were chosen for which 18 tests were conducted with central square holes of variable thicknesses and sizes, and the remaining 6 holes centrally cut from the webs. A total number of 24 tests were performed using lipped program aiming to determine the ultimate shear strengths of high strength cold formed steel channels with central square holes, Article 106647, Thin-Walled Structures, Vol. 149, April 2020, https://doi.org/10.1016/j.tws.2020.106647

ABSTRACT: Oxygen-free copper (OFC) has been increasingly used in engineering applications due to many advantageous properties. In order to investigate the flexural buckling behaviour of OFC tubular columns under axial compression, seven full-scale specimens were tested. The buckling failure modes of the specimens were analyzed, and the flexural buckling strengths were obtained. Subsequently, two finite element models were developed and verified against the test data. A parametric study was performed as well. The results showed that the OFC columns with small slenderness failed by elastic-plastic buckling, while those with high slenderness failed by elastic buckling. Eqs. (9) and (11), which are based on the Perry formula, suitably described the buckling curves of the OFC tubular columns. The value of a in Eq. (9) was 0.293; and the values of a1, a2 and a3 in Eq. (11) were 1.647, 1.041, and 0.175, respectively.

ABSTRACT: In this paper, the crushing behaviors of composite pre-folded tubes made of KFRP/CFRP hybrid laminates subjected to quasi-static axial loads are investigated both experimentally and numerically. The full-diamond origami pattern and its variation forms with curved lobes are considered for the tube design. Five pre-folded tube specimens with different ply stacking sequences consisting of CFRP and KFRP woven fabrics are manufactured and tested in quasi-static axial compression tests. The finite element models for pre-folded tubes made of KFRP/CFRP hybrid laminates are developed and validated with the experimental results. A comprehensive parametric study on the energy absorption properties of CFRP/KFRP hybrid composite tubes with various geometries is performed numerically. The results show that the energy absorption performance of the composite tubes has a strong correlation with the composition of hybrid fiber and the specimen with the stacking sequence of [theta(k), theta(c), theta(c), theta(k)] has the best overall energy absorption performance among the five specimens tested. Moreover, it is found that by converting the standard full-diamond pattern to the curved variation forms, the energy absorption performance of the pre-folded tubes can be improved.

“Shear tests and design of cold-formed steel channels with central square holes”, Article 106650, Thin-Walled Structures, Vol. 149, April 2020, https://doi.org/10.1016/j.tws.2020.106650

ABSTRACT: In the latest North American Specification S100:2016 Edition and the most up-to-date Australian/New Zealand Standard AS/NZS 4600:2018, the Direct Strength Method (DSM) shear design rules for unperforated channel sections have been adopted. To date, for perforated sections, there is no DSM design rule for shear in the current Specification/Standard while the conventional reduction factor method is still in use to calculate shear strengths for these sections. This paper summarises the test results in an experimental program aiming to determine the ultimate shear strengths of high strength cold-formed C-sections with square holes centrally cut from the webs. A total number of 24 tests were performed using lipped channel sections in which 18 tests were conducted with central square holes of variable thicknesses and sizes, and the remaining 6 were tested with no holes in the webs. Three different section thicknesses and square hole sizes were chosen for...
investigation in this study. In addition, Finite Element Method (FEM) analysis was initially developed to validate against test results, and the accurate results from the FEM were then employed in a parametric study for the extension of test data by varying the section thicknesses and the hole sizes. In the DSM shear design equations, two inputs namely the shear buckling load, \( V_s \), and the shear yielding load, \( V_y \), are required. The numerical solutions for \( V_s \) for whole sections with central square holes have been proposed by first author in previous research studies. For \( V_y \) in this paper, a new and simplified model is proposed based on net web areas. Recommendations for an extension to the DSM shear design rules for channel sections with square holes up to certain hole size limit are given.

ABSTRACT: The interaction between steel and concrete is important for the functionality of composite tubular construction. In this study, a series of pushout tests were carried to investigate the behaviour of steel tubes to sandwiched concrete interfaces in concrete-filled double skin steel tubes (CFDST). Parameters concerned included the diameter to thickness ratio of both outer and inner steel tubes, the hollow ratio of the cross section, the roughness of steel tube surfaces, the shrinkage of concrete, etc. The bond stress-slip relationships and the strain responses were recorded and analysed, and effects of different parameters were discussed. In general, the bond strength of the outer steel tube to concrete interface for CFDST was comparable with that of concrete-filled steel tube (CFST), and the bond strength of the inner steel tube to concrete interface was higher than that of the outer steel tube to concrete interface.

ABSTRACT: Localised/partial loading is seen in many applications in the building and construction industry. This paper aims to study the influence of localised loading in different positions and Loading Coverage Areas (LCAs) for steel columns with concrete and timber inﬁlls, and hollow steel tubes. Fifteen tests were carried out in three categories. Structural stability of the specimens was evaluated far into their plastic response until crushing. The energy absorption of each specimen was quantiﬁed and compared with its counterparts of different materials and LCAs. Axial capacity and failure were focused on as well as the strength-to-mass ratio for each specimen. There was a noticeable capacity difference between the side-loaded and mid-loaded specimens of each group indicating the effect of material under loading on the capacity. The side-loaded specimens had a higher interface between the loading element and steel, compared to the mid-loaded specimens. Numerical analysis was also conducted, which yielded a very close consistency of results with the experiments.

ABSTRACT: This paper describes an experimental study on the flexural and eccentric compressive behavior of concrete-filled square steel tube (CFSST) beam-columns stiffened with PBL stiffeners. Three types of CFSST beam-columns were fabricated and tested under the flexural moment and eccentric compressive load. Among the three types of columns, the two types of columns were strengthened with the PBL and steel plate stiffeners; the other type of columns was not strengthened. In addition, extensive finite element analyses (FEA) were
carried out to evaluate the stress distribution. Flexural test results show that failure modes of specimens without stiffeners were different from specimens with the PBL or steel plate stiffeners. The results also demonstrate the distribution of cracks in the concrete was affected by stiffeners and the columns with the PBL stiffeners have the most uniformed crack distributions. The capacity improved by the PBL stiffeners was insignificant. However, the flexural stiffness of the specimen stiffened with the PBL stiffeners was about 20% larger than the unstiffened specimen. Eccentric compressive load test results show the capacity of specimen with the PBL stiffeners was 6.95% larger than the unstiffened specimen. The eccentric compressive capacity decreased with the increase of the eccentricity ratio or slenderness ratio. FEA results show that stiffeners can effectively improve the mechanical behavior of CFSST specimens under bending and eccentric compressive loads.

ABSTRACT: When loading experiments are repeated on different samples, qualitatively different results can occur. This is due to factors such as geometric imperfections, load asymmetries, unevenly stressed regions or uneven material distributions created by manufacturing processes. This fact makes designing robust thin-walled structures difficult. One numerical strategy for exploring these different possible responses is to impose various initial imperfections on the geometry before loading, leading to different final solutions. However, this strategy is tedious, error-prone and gives an incomplete picture of the possible buckled configurations of the system. The present study demonstrates how a deflation strategy can be applied to obtain multiple solutions for the more robust design of thin-walled structures under displacement controlled uniaxial compression. We first demonstrate that distinct initial imperfections trigger different sequences of instability events in the Saint Venant–Kirchhoff hyperelastic model. We then employ deflation to investigate multiple bifurcation paths without the use of initial imperfections. A key advantage of this approach is that it can capture disconnected branches that cannot easily be discovered by conventional arc-length continuation and branch switching algorithms. Numerical experiments are given for three types of aircraft stiffener profiles. Our proposed technique is shown to be a powerful tool for exploring multiple disconnected bifurcation paths without requiring detailed insight for designing initial imperfections. We hypothesise that this technique will be very useful in the design process of robust thin-walled structures that must consider a variety of bifurcation paths.

ABSTRACT: A circular bio-inspired in-plane gradient core is designed based on the Royal Water Lily venation structure. The dynamic responses of various clamped circular sandwich panels with the bio-inspired gradient core under blast loadings are investigated using a combined numerical and theoretical approach. Four groups of gradient cores, such as negative, hybrid, non-gradient, and positive cores, are obtained by adjusting cell wall thickness. The classical circular sandwich panel model under blast loading is modified by introducing the in-plane gradient of the core. The blast resistance of the in-plane gradient clamped circular sandwich panels are studied using the modified theoretical model. Simulation results are consistent with the theoretical predictions for clamped circular sandwich panels with various gradient cores. In comparison with other three kinds of gradient sandwich panels, the proposed sandwich panels with negative gradient cores have higher specific energy absorption and lower deflection of the back face sheet. Results show that a reasonable design of the density of the gradient core can effectively improve the mechanical behaviors of the sandwich structure without adding additional mass in the structure. Such results can provide guidance for the in-plane design of sandwich structures.

ABSTRACT: This paper aims to investigate the performance of an aluminum–rubber composite plate under impact loading. The impact resistance of the plate has been evaluated using both experimental and numerical methods. The experimental tests were carried out using gas gun at velocities of 75, 101, 144 and 168 m/s. The energy absorption of composite plates has been closely examined for all samples. The effect of rubber layer positioning either on front face or on back face of the aluminum plate was also evaluated. It was found that the composite plate with rubber on front face provides higher performance to absorb the energy. In parallel to the experiment, a finite element model was created using the finite element software LS-DYNA to simulate the response of the aluminum–rubber composite plate under a high energy rate loading condition. The data obtained from finite element modeling shown a close agreement with the experimental results in terms of failure mechanism and energy absorption. In addition, a parametric study was carried out incorporating different impact velocities, rubber formulation, rubber layer thickness, interface bonding strength between rubber and aluminum layers and ballistic performance of aluminum-rubber sandwich panel. It was concluded that by increasing the rubber layer’s thickness the energy absorption of the composite plate will be increased, especially when rubber layer placed in front face of the aluminum plate. Although at high interface bonding of rubber and aluminum layer, the composite with rubber layer in front face has better performance, but low bonding of interface lead to higher energy absorption in back face configuration.

ABSTRACT: A comprehensive experimental programme was contrived with the aim of investigating the behaviour and the capacity of cold-formed steel built-up columns with particular emphasis on the effects of connector spacing and contact between individual components. A total of 24 built-up columns, including four different cross-sectional geometries, were tested between pin-ended boundary conditions, while applying the load with nominal eccentricities of L/1000 or L/1500. The columns were designed to fail by interaction of cross-sectional buckling of the components, possible global-type buckling of the components between connectors and global buckling of the whole column, and all these failure modes were successfully achieved. The built-up sections were fabricated from flat plates, plain channels and lipped channels and were assembled with either bolts or self-drilling screws. The connector spacing was varied between specimens of the same cross-sectional geometry. Tensile coupons were taken from the flat portions and the corners of the sections in order to determine their material properties, while detailed measurements of the geometric imperfections of each specimen were also carried out using a specially designed measuring rig. In addition, the isolated behaviour of both the bolts and the screws used in the specimens was investigated through single lap shear tests. It was observed that the buckling patterns in the built-up specimens were affected by contact between the various components and by the spacing between the connectors. However, in the cases where global buckling of the components in between connector points was not critical, the connector spacing had a minor influence on the ultimate capacity of the columns.

Strength design of welded high-strength steel beams considering coupled local and global buckling”, Article 106391, Thin-Walled Structures, Vol. 149, April 2020, https://doi.org/10.1016/j.tws.2019.106391

ABSTRACT: High-strength steel (HSS) is gaining increasing use in modern building construction for several reasons, the most notable being that its increased strength can lead to a reduction in self-weight and correspondingly reduced emissions and waste during its manufacture. However, there is little guidance available in design standards when the steel grade exceeds 690 MPa. Such guidance is needed, because the use of thinner plate elements than would normally be encountered in mild steel members leads to an increased
importance in local plate buckling participating in the strength limit state, and its interaction with yielding and residual stresses that are germane to HSS members. This paper investigates the buckling strength of welded HSS I-beams numerically, and based on the results of the study it proposes a corresponding strength design criterion that incorporates local buckling and lateral-torsional buckling and their interaction at the ultimate limit state. The finite element model used for the analysis is based on ABAQUS software, and it incorporates the interaction of elastic buckling, yielding, residual stresses induced by welding and geometric imperfections. The numerical formulation is validated against test results reported by several investigators, and it is then used to produce a substantive set of data to investigate the buckling strength of welded HSS beams. It is shown that the buckling strength depends primarily on two parameters: the generalised (or member) slenderness and the section slenderness. It is also demonstrated that coupled modes of failure are possible for slender sections that incorporate the interaction of local and lateral-torsional modes, which traditionally are treated simplistically in current steel design standards by using effective section properties. To overcome the limitations on guidance for the strength design of HSS beams, a set of new strength design equations are proposed from the numerical data, based on the generalised and section slendernesses.

ABSTRACT: The efficient Wave-Based Method (WBM) is extended to predict the bending vibration response of thin-walled rectangular plates under thermal load. Governing equations of dynamic plate bending problems considering thermal effects are first introduced. The general solution and particular solution of governing equation are derived by the separate variable method and residue theorem, respectively. Then novel wave functions and particular solution function are selected to establish the wave-based model of dynamic plate bending problems under thermal load. The accuracy of WBM is verified by finite element method (FEM) for a simply supported plate and a clamped plate. Then the influence of thermal load on the dynamic bending responses of a clamped plate is investigated. Simulation results prove that WBM achieves higher convergence rate than FEM. The thermal load significantly changes the structural dynamic behaviors. When both the temperature-dependent material properties and thermal stresses are considered, the increase of environment temperature leads to the resonant peak of displacement response shifts toward lower frequency.

ABSTRACT: The propagation of stress waves in an impulsive load-excited fluid-filled cylindrical structure containing an internally clamped shell is investigated. The external and internal cylinders are made of functionally graded and homogeneous isotropic materials, respectively. The space between the cylindrical shells is filled with a non-viscous and compressible fluid. The equations of motion for solid media are based on the three-dimensional theory of elasticity. According to the problem definition, for establishing the relationship between the displacement and stress fields, the governing equations are extracted in the form of plane-strain. A laminate model is employed to attain the dynamic equations of the functionally graded cylinder. Next, a transfer matrix is established by considering the continuity conditions of the stress and displacement at the interfaces of the layers. Then, the Laplace transform is utilized to transfer wave equations from the time domain to the Laplace domain. Eventually, a numerical inverse Laplace transform known as the Durbin method is employed to retrieve the solutions obtained into the time domain. An excellent agreement is observed in comparing between results of the present analytical method and previous models. Next, the effects of geometrical and physical properties of the inner shell on the transient response of the functionally graded cylinder are investigated. Also, the von Mises stress as the most effective parameter in the structural design is studied. The results show that the inner shell made of a material with a lower elasticity modulus leads to a reduction in the
amount of von Mises stress in the external cylinder. As well as, an inner shell with a greater volume has a more positive effect on the transient response of the functionally graded cylinder.

ABSTRACT: Free vibration analysis is carried out for piezoelectric coupled carbon nanotube (CNT)-reinforced composite cylindrical shells with the influences of various boundary conditions and hygrothermal environmental conditions for the first time. A simple and effective non-iterative mathematical method is used to calculate the natural frequencies. The equilibrium equations of motion are obtained based on the first-order shear deformation shell theory with the coupling effects of piezoelectricity, temperature, and moisture, respectively based on the Maxwell equation, the Fourier heat conduction equation, and the Fickian moisture diffusion equation. The Mori-Tanaka micromechanics model is used to estimate the resulting material properties for a composite shell reinforced with CNTs. Presented methodology and attained results are validated with the existing results in the literature. The effects of the boundary conditions, lamination stacking sequence, volume fraction and orientation of CNTs, piezoelectricity, and geometry of the shell on the natural frequencies of the shell are investigated. A moderate effect of temperature/moisture variation on the natural frequencies is also observed. It is found that the influence of structural boundary conditions is more significant at higher CNT volume fractions and for thicker and shorter shells, and the piezoelectricity effect is more obvious at higher circumferential mode. The model and results presented in this study can be utilized to determine vibration characteristics of smart CNT-reinforced composites subjected to hygrothermal loading as well as mechanical loading.

ABSTRACT: This paper carries out the nonlinear stability of nanocomposite multilayer organic solar cell (NMOSC) subjected to axial compressive loads. The model of organic solar cell is assumed to consist five layers: Al, P3HT:PCBM, PEDOT:PSS, IOT and Glass. Based on the classical plate theory, the basic equations are established taking into account the effect of elastic foundations and initial imperfection. The approximation solutions are selected based on the boundary conditions of the four edges of NMOSC. The equation which indicates the relationship between axial compressive loads and deflection amplitude of NMOSC is obtained by using the Galerkin method. Bees Algorithm is applied to maximize the value of critical buckling load with nine variables including the thickness of five layers, the length and the width of NMOSC and two stiffness coefficients of elastic foundations. The numerical results show the effect of geometrical and material parameters, initial imperfection and elastic foundations on the nonlinear static stability and the critical buckling load of NMOSC. Optimal values of nine geometrical parameters of NMOSC are also determined.

ABSTRACT: Faced with the large annual output of construction and demolition waste, cyclic utilization of recycled coarse aggregate (RCA) is inevitable. This study uses steel-fiber-reinforced recycled aggregate concrete (RAC) in the manufacture of concrete-filled steel tube columns, to improve the utilization of RCA. A comprehensive study of the axial behavior of 54 steel-fiber-reinforced self-stressing recycled aggregate
concrete-filled steel tube (SSRCFST) columns was conducted. The variables in the experiments included the steel fiber content, self-stress, quality replacement rate of RCA, concrete strength grade, and steel tube thickness. The experimental results show that a poor concrete strength is obtained with increasing RCA content. However, under tri-axial stress in the steel tube, the negative influence of RCA is weakened. An enhancement of the ductility of SSRCFST columns can be achieved by adding a moderate amount of steel fiber. Self-stress can significantly improve the ultimate capacity and stiffness of SSRCFST columns. Moreover, design equations for the ultimate capacity of SSRCFST columns are proposed, and the predictions agree satisfactorily with the experimental results.

Chengqiang Ge, Qiang Gao, Liangmo Wang and Zhong Hong (Department of Mechanical Engineering, Nanjing University of Science and Technology, Nanjing, PR China), “Theoretical prediction and numerical analysis for axial crushing behaviour of elliptical aluminium foam-filled tube”, Article 106523, Thin-Walled Structures, Vol. 149, April 2020, https://doi.org/10.1016/j.tws.2019.106523

ABSTRACT: Dynamic crushing behavior of elliptical aluminium foam-filled tube (EFT) under axial impact was analyzed thoroughly. First, the deformation mechanism of EFT is investigated. Based on this, a theoretical model to predict the mean crushing force is established under some specific assumption. The interaction work between the foam and tube are introduced in the model to improve the accuracy. Further numerical simulations of the EFT are conducted to validate the theoretical models which indicates the theoretical model is pretty accurate. Finally, the influence of the geometric parameters of EFT on the mean crushing force is also revealed. The study aims at quantifying the energy absorption of EFT under axial impact loading, for variations in the geometry parameters of the tube. This can guide the engineers to design great energy absorber more efficiently.

ABSTRACT: In this paper, a comprehensive experimental study on cylindrically curved steel panels is presented, in order to characterize the structural behavior of cylindrically curved panels as individual members under uniform compression. Therefore, 32 full-scale compression tests on both stiffened and unstiffened simply supported curved panels were performed, where the radius of curvature and the number of stiffeners were varied. Based on the experimental results a numerical model is built, which was used to investigate the sensitivity to initial geometric imperfections of curved panels. One of the main conclusions is that the behaviour of a panel highly depends on the shape of the initial geometric imperfections, which also determines its ultimate resistance.

ABSTRACT: A theoretical approach is presented to derive an explicit formula for buckling load and postbuckling path of advanced grid stiffened conical shells (stiffeners with laminated composite skins). Different types of fiber paths of grids including stringer, ring, and helical are considered. The simply supported truncated conical shell with imperfection is subjected to axial compression. Basic formulations are constructed using the classical theory of shells and von Karman type of nonlinear strain-displacement relationships. The equilibrium and compatibility equations are solved by Galerkin procedure, and an explicit relation is obtained to predict the equilibrium paths. Results for different conditions are verified by comparison to existing data in the literature. Novel results are revealed in the parametric study to show the effects of different fiber paths, geometrical conditions, and lay-up configurations on the buckling and postbuckling of the advanced grid
stiffened structures. As a key finding, the helical and ring fibers of grids are more effective than stringer on the buckling load and postbuckling path. Especially when high number of ribs are considered.

ABSTRACT: Special-shaped welded hollow spherical joints (WHSJ) are increasingly used in several important spatial grid structures. The corrosion of WHSJ is inevitable and can eventually threaten structural safety. There is no research or comparison on the compressive strength of corroded special-shaped WHSJ. Therefore, through the simulation and analysis of the corrosion depth, corrosion mode, corrosion size, joint size, and steel material, the compressive strength of three types of special-shaped WHSJ after corrosion was studied, and the corresponding evaluation method for compressive strength was established. Results indicated that the loss of wall thickness ($T_c/T$) and the ratio of grooving corrosion ($2W_c/D$) were the key factors affecting the compressive strength of the special-shaped WHSJ after corrosion. The effect of corrosion on the bearing capacity was related to the size ratio ($d/D$), WHSJ connected by the H-beam were most affected by corrosion; the failure mode was basically buckling failure, but punching failure might occur in the H-beam WHSJ. The results obtained could form the basis for the selection of the WHSJ shapes and the evaluation of the bearing capacity of the space grid structure with special-shaped WHSJ after corrosion.

ABSTRACT: This paper addresses lateral torsional buckling of coped beams with corrugated webs. ABAQUS is the finite element software package used to develop three-dimensional models to investigate the influence of copes on the lateral torsional buckling resistance of this type of beams. It is found that the ultimate capacity of beams is remarkably reduced by 40%–80% depending on the cope geometry. The reduction in the capacity depends on the cope length and cope depth compared to the capacity of un-coped corrugated web beams. The coped beams with corrugated webs still exhibit a greater capacity than do the corresponding coped beams with flat webs. Design equations are developed to depict the strength of coped beams with corrugated webs. In addition, due to the low stiffness in the longitudinal direction of the corrugated beams and the absence of the flange in the coped region, the web has a tendency to elongate, and the corrugations are flattened. This phenomenon affects displacements both vertically and laterally and results in large deformations that are not acceptable in engineering practice. Strengthening solutions are introduced in this study to solve this problem.

ABSTRACT: Steel modular construction has the potential to meet the growing infrastructure needs of the big cities and hence, the demand for modular construction is on the rise. This paper introduces a unique and innovative modular construction technique which involves the use of thin-walled hollow structural steel members and a state-of-the-art cast-steel connector, namely VectorBloc connector. The performance of the beam-column connections to be used in this modular construction largely determines its performance and success. In the present study, uniaxial and biaxial bending behavior of a typical corner beam-column connection made of thin-walled hollow structural steel members and VectorBloc connector was studied through full-scale tests and nonlinear finite element method. This beam-column connection will be used for constructing an assisted living facility. This study concludes that the design loads of the proposed assisted living facility can be safely carried by the VectorBloc connection. However, the weight of the VectorBloc connector can be reduced to 80% without compromising the design requirements of the assisted living facility. This study also concludes that the VectorBloc connection can be considered as a rigid connection. However, effective bracings against horizontal displacements must be provided in the structure in which the connection is intended to be used.
coupon tests, and the models were validated. Next, a parametric study was carried out, considering the residual stresses, geometric imperfections, and stress–strain curves obtained from the tension coupon tests, and the models were validated. A parametric study was carried out to generate additional experimental and numerical data, including overpressure–time histories, strain–time histories, and permanent displacement at different locations, were recorded. The response patterns of the specimens were identified and discussed, and the critical wrinkle strains were calculated based on the tension field theory. To elucidate the effects of the length/width ratio on the wrinkling behavior, wrinkling experiments were performed on specimens with four different length/width ratios but the same thickness. In addition, the surface and internal in-plane stresses of the structures were determined by both three-dimensional DIC and the digital gradient sensing method. The results indicated that a stress-change occurs between the membrane surface and its inner structure. Finally, the critical shear displacements determined using the two methods were found to be very close.

ABSTRACT: The dynamic performance of single-layer reticulated domes under explosions was analysed experimentally and numerically in this study. The loading was generated by a Gas Blast Shock loading system (GBS) by igniting a gaseous mixture and applying it to the reduced-scale structure to investigate the dynamic response modes. Acetylene/air mixtures with various volumes were designed in different cases. The experimental data, including overpressure–time histories, strain–time histories, and permanent displacement at representative locations, were recorded. The response patterns of the specimens were identified and discussed, and the five major failure modes are as follows: no damage mode, insignificant damage mode, moderate damage mode, heavy damage mode, and whole collapse mode. It was shown that the Gas Blast Shock loading system is feasible for studying the response modes of single-layer spherical reticulated shells under external explosion. In addition, a numerical model based on ANSYS/AUTODYN was developed to simulate the experimental tests, and an improved equivalent TNT method was used to simplify the loading system. Good agreement between the experimental and numerical results was achieved and an explosion efficiency factor was proposed.

ABSTRACT: This study describes an experimental and numerical modelling investigation of the buckling behaviour and load-carrying capacities of pin-ended hot-rolled high-strength structural steel equal-leg angle section columns. The testing programme involved material testing, measurements of the initial geometric imperfections, and 48 pin-ended column tests. The non-linear finite element models were developed considering the residual stresses, geometric imperfections, and stress–strain curves obtained from the tension coupon tests, and the models were validated. Next, a parametric study was carried out to generate additional
numerical data. The experiment and numerical results were analysed in detail and then utilised to evaluate the accuracy of the established design rules in China, the USA, and Europe. Through an in-depth comparative study, it was proved that the prediction of the compressive load-carrying capacity of high-strength steel angle section columns, using code GB50017, is relatively accurate.

ABSTRACT: This study investigates the stability loss of thin walled conical shell structures under axial loading. More specifically, conical shells with semi-vertex angle greater than 65 degrees and with different bottom edge radial stiffness were studied in order to fill the gap in existing literature. The effects of geometrical parameters of the structure on the load bearing capacity were determined. Conical shell structures with high semi-vertex angle and different boundary conditions display highly non-linear character under axial loading, hence conventional analytical approaches are not adequate to predict the limit load. Therefore, a new method was proposed in this study which can accurately predict the limit load of these structures. The deviation between the proposed method and numerical results was found to be plus or minus 13%, while it was one order higher (plus or minus 300%) in classical shell theory, based on the configuration. Furthermore, similarity parameters were suggested to increase the range of application of the proposed method. Similarity parameters enable researchers to work with scaled-down models which are capable of simulating the behaviour of real-time-scale models. In addition, the effect of geometrical initial imperfections on the load bearing capacity was investigated and a new reduction coefficient was identified which is much more accurate compared to the overly conservative standard counterpart. A numerical model was developed with COSMOS/M software. This model was validated with experiments, and then was used for the parametric study.

ABSTRACT: This paper investigates the mechanical behavior of hybrid structures under the quasi-static axial loading. The hybrid tubes with different configuration scheme, stacking sequence and foam filler are first used to perform the quasi-static axial compression tests. In addition, the tubes with aluminum, Carbon Fiber Reinforced Plastic (CFRP) and aluminum foam are also tested as a comparison of the hybrid tubes. It was found that both the empty and foam-filled aluminum/CFRP hybrid tubes showed better mechanical behavior characteristics. Based on the numerical modeling, the results have been confirmed by experiments. Furthermore, a parametric study is carried out to explore the effects of relevant parameters on the mechanical behaviors of the hybrid tubes, and some useful conclusions are achieved.

ABSTRACT: The low velocity impact performance of curved steel-concrete-steel (CSCS) sandwich shells with bolt connectors subjected to a hemi-spherical head drop hammer was investigated in this paper. Experimental results including impact force history, displacement history and permanent deformation were analyzed to reveal the influences of concrete core and steel plate thickness as well as shear connectors’ spacing on the impact performances of CSCS shells. The impact process consisted of three stages, i.e., inertial stage, loading stage and unloading stage. Meanwhile, three failure types were observed from the nine specimens subjected to impact load. They were plastic deformation of steel plate without fracture (Failure type I), fracture of steel plate (Failure type II) and penetration of steel plate (Failure type III). The presence of bolt connectors was proven to be an effective way to prevent the detachment of steel plates from concrete core. Moreover, finite element (FE)
method was used to simulate the CSCS shells subjected to impact load. The accuracy of the FE model was verified by comparing the impact load history, displacement history and failure type from FE simulations with test results. It turned out that concrete core was the main part to dissipate impact energy, followed by top steel plate and bottom steel plate.

ABSTRACT: The present paper investigates the wind-induced buckling and vibration of cylindrical storage tanks based on wind tunnel experiments and time-history response analysis. Focus is on the effect of the vibration of tank shells on the buckling behavior. The dynamic buckling loads obtained from the experiments and the time-history response analysis are compared with the results obtained from the static buckling analysis. The effect of the inertia force generated by the vibration on the dynamic buckling behavior is found to be fairly small. Finally, the dynamic buckling loads are evaluated based on the results of the analysis for static wind loading.

ABSTRACT: As a first endeavour, the out-of-plane vibration characteristics of laminated functionally graded graphene platelets reinforced composite (FG-GPLRC) curved beams bonded by piezoelectric layers are investigated. The displacement components are approximated through the beam thickness direction based on the first-order shear deformation theory (FSDT). Accordingly, the shear deformation and rotary inertia effects due to both the torsional and flexural deformations are considered. The effective mechanical properties of the nanocomposite layers are estimated using the modified Halpin-Tsai model. The governing equations are derived by employing Hamilton's principle, which are discretized in the spatial domain using the differential quadrature method (DQM). After validating the approach, some useful results are provided which can be used for future researches. In this regards, the effects of graphene platelets (GPLs) distribution patterns, GPLs weight fraction and dimensions, number of GPLs reinforced layers, piezoelectric layer thickness, the curved beam geometric parameters and boundary conditions on the vibrational characteristics of the laminated FG-GPLRC curved beams embedded in piezoelectric layers are studied.

ABSTRACT: In this work, an efficient four-node facet shell element is presented for analysis of doubly curved multilayered piezoelectric shells, based on an electromechanically coupled third order zigzag theory. It is motivated by the excellent performance of the shell element developed earlier by the authors for elastic laminated shells. The laminate theory not only incorporates a layerwise description of the inplane displacements but also accounts for the layerwise normal deformation due to the d33-effect of the piezoelectric layers. The number of primary displacement variables is, however, the same as for the smeared third order theory (TOT). A quadratic variation of the electric potential across the piezoelectric layers is assumed, while satisfying the equipotential condition of electroded piezoelectric surfaces using the concept of electric nodes. The performance of the element is assessed for the stress analysis under mechanical and electric potential loads, and for the free vibration response of hybrid piezolaminated deep shells in comparison with the three dimensional piezoelectricity based analytical and finite element solutions. The comparison shows excellent accuracy of the present element for the deflection, stresses, sensory potential, electric displacement and natural frequencies of hybrid shells made of composite as well as the highly inhomogenous soft-core sandwich laminates, for which
the smeared TOT is shown to produce highly erroneous results. It is also shown to yield better accuracy than the other available elements of similar computational efficiency for hybrid composite shells.

ABSTRACT: Fibre reinforced cementitious composites (FRCC) hollow tube is a kind of promising high-toughness energy absorption structure. As this structure absorbs energy via the transverse deformation of tube, it is necessary to investigate the transverse compressive behavior and failure mode of the FRCC tubes. In this study, the transverse compressive response of cementitious composites tubes reinforced by Polyvinyl alcohol (PVA) fiber and ultra-high molecular weight polyethylene (PE) fibre, respectively, has been experimentally investigated, numerically simulated and dimensionally analyzed. According to the transverse compression tests, the FRCC tubes failed with four-hinge fracture. The FRCC tubes presented ductile fracture while the plain cement-based material (P0) tube presented brittle fracture. The numerical simulation based on extended finite element method (XFEM) has a good agreement with the experimental measurements, and both the crack development at the hinges and stress distribution on the crack section are predicted. The fibre reinforcements remarkably enhanced the mechanical properties of tubes, including the transverse force resistance and deformation capacity. The peak force and maximum energy absorption of FRCC tube is 2 times and 60 times higher than those of P0 tube, respectively. The dimensional analysis suggested that the specific energy absorption per unit volume was principally dominated by the ratio of tube thickness to average radius, whereas the stroke efficiency was governed by the ratio of tube thickness to average radius and the ratio of average radius to tube length. This work provides a guidance for developing FRCC tubes with high specific energy absorption, and is expected to widen the applicability of FRCC tubes in protection engineering.

ABSTRACT: In the present paper, an attempt has been made to obtain the solution for bending and stress under the thermal environment using Galerkin Vlasov's method. A non-polynomial based higher-order shear deformation theory with inverse tangent hyperbolic shape function is used to define the displacement field. The formulation is performed for the author's recently developed sandwich plate using a new modified sigmoid function-based functionally graded material (S-FGM) plate of different symmetric and non-symmetric configurations. Using a one-dimensional steady-state heat conduction equation, a new temperature distribution through the thickness based on modified sigmoid law is proposed. Three different types of porosity are considered viz. even, uneven but symmetric and uneven but non-symmetric. A new uneven non-symmetric porosity model is used in which micro-voids are varied in accordance with material property variation in the thickness direction in order to capture the accurate distribution of voids on the plate. The principle of virtual work is employed to derive equilibrium equations. An exact solution is obtained using the assumed solution with shape functions satisfying the edge boundary conditions. From the present study on static analysis, it is deduced that more refined and accurate results for plate in thermal environment, it is necessary to include the thermal effect on the stiffness of the plate in addition to the initial deflection of the plate. The effect of boundary conditions on stress and deflection distribution along the surface of the porous plate is studied, and it is observed that the distribution is prominently affected by the type of symmetric or asymmetric boundary conditions. The considerable increase in deflection and stress can be seen for even porosity distribution (P-1) in
comparision to uneven symmetric (P-2) or uneven non-symmetric (P-3) porosity distribution. In addition, the maximum transverse shear stresses are offset more from the center of the sandwich plate with an increase in temperature differences with a maximum offset at $\Delta T = 300 \text{ K}$ and minimum offset at $\Delta T = 0 \text{ K}$. Different examples are considered to check the accuracy and validation of the present formulation. The calculated outcomes and interpretations can be useful as a validation study for the imminent investigation of sandwich SFGM plates having porosities in the thermal environment.

ABSTRACT: This study investigates the crush response of lattice filled square tubes under quasi-static compressive loading. Auxetic lattice (auxetic strut and re-entrant) filled tubes have been compared to a non-auxetic (honeycomb) filled alternative and an empty tube. All structural lattices within this study were designed to be of equal mass. The experimental results were computationally validated using Abaqus®/Explicit. Experimental and numerical results show good agreement which highlights that the addition of lattice structures greatly improved the crashworthiness performance of the crash tube compared with an empty tube. By comparing the experimental values of energy absorption (EA), through the inclusion of a filler lattice a 62.6%, 64.0% and 79.1% increase over the empty tube were obtained for the auxetic strut, re-entrant and honeycomb structures respectively.

ABSTRACT: This is the first research on the free vibration analysis of functionally graded graphene platelets reinforced composite (FG-GPLRC) viscoelastic annular plate resting on the visco-Pasternak foundation and subjected to the nonlinear temperature gradient and mechanical loading within the framework of higher-order shear deformation theory (HSDT). Hamilton’s principle is employed to establish governing equations within the framework of HSDT. In this paper, viscoelastic properties are modeled according to Kelvin-Voigt viscoelasticity. The deflection as the function of time can be solved by the fourth-order Runge-Kutta numerical method. Generalized differential quadrature method (GDQM) is applied to obtain a numerical solution. Numerical results are compared with those published in the literature to examine the accuracy and validity of the applied approach. A comprehensive parametric study is accomplished to reveal the influence of the stiffness of the substrate, patterns of temperature rise, axial load, damper and viscoelasticity coefficient, weight fraction and distribution patterns of GPLs and geometric dimensions of GPLs on the frequency response of the structure. The results revealed that applying sinusoidal temperature rise and locating more square-shaped GPLs in the vicinity of the top and bottom surfaces have important effect of the highest natural frequency and buckling load of the FG-GPLRC viscoelastic structure.

ABSTRACT: This paper investigates the collapse behavior of square paper tubes and the influence of tensile-compressive yield asymmetries of paper tube materials by combining the theoretical and experimental methods. An approximate energy absorption theoretical model is developed to predict the mean crushing force of square paper tubes subjected to axial loading. Besides, combined with the remarkable linear regularity of the experimental results, the numerical curve of the effective crushing distance ratio of paper tubes is obtained to improve the applicability of the proposed model. Then the theoretical results taking account of effective
crushing distance are in excellent agreement with the experimental results. The proposed model can be used not only for the prediction of energy absorption characteristics of paper tubes in a logistics environment, but also to guide the protective packaging structure design with paper tubes.

ABSTRACT: This study investigated the buckling performances of stainless steel toroidal shell segments under uniform external pressure. The toroidal shell segments used in this study exhibited a nominal section radius of 70.5 mm, nominal wall thickness of 1.346 mm, and nominal rotation radius of 138 mm. A total of 12 toroidal shell segments were manufactured using roll bending and were measured geometrically, tested hydrostatically, and evaluated numerically. Six of the shell segments had a 45° rotation angle, whereas the other six had a 90° rotation angle. Moreover, the buckling of geometrically perfect toroidal shell segments was explored under various rotation angles ranging from 30° to 360°.

ABSTRACT: Thin–walled rectangular tube bent parts of continuous varying radii are widely used in aircraft, aerospace, aviation, radar, and several high-tech industries to save space and satisfy the internal structure compact of the specific products. In the previous years, the applications of thin-walled rectangular tubes were hindered because of the distortion in the cross-section area, which occurred during deformation. Nevertheless, due to its unique characteristic, free bending technology is highly suitable to form tubular components with a variable bending radii and bends in several planes. Thus, in this study, the deformation behavior of a thin-walled tube (with a rectangular cross-section area) of continuous varying radii during free bending technology was investigated. Besides, a stress analysis model was proposed to predict the equivalent stress and strain distribution. The proposed model was verified using simulations and experimentation. Furthermore, the influence of two key parameters (feeding speed and fillet radius) on the formability of a thin-walled rectangular tube was discussed. The remarkable results obtained from this study verify that free bending technology is a significant forming technology to manufacture rectangular thin-walled tubes with continuous varying radii.

ABSTRACT: The wind uplift performance of the continuously welded stainless steel roof (CWSSR) system adopted in the Zhaoqing New District Sports (ZNDS) Center of China is investigated in this study. To determine the optimal welding program and examine the mechanical properties of the continuously welded stainless steel joints, uniaxial tensile testing is first conducted on 27 specimens with tension-shear and tension-bending types. Two CWSSR specimens, one that is square-shaped with a horizontal layout and one that is rectangular-shaped with an inclination layout of 10.71°, are further tested under dynamic and static ultimate wind uplift loadings to explore the wind uplift capacity. All specimens are full-size, and the corresponding materials, structural details and construction technologies are kept the same as the actual building to ensure the authenticity of the testing investigations. The testing results indicate that the integrated and sealed CWSSR system has a clear force transmission mechanism and a remarkable wind resistance performance. The welded joints achieve the best performance, and the mechanical behaviours are equivalent to those of the base material under the continuously welded conditions including an electric current of 65 A and a moving velocity of 750 mm/s. An excellent dynamic wind suction performance is achieved under 5000 five-level cumulative loading cycles with a maximum pressure of 5400 Pa. The static ultimate pressure reaches 9400 Pa for the square specimen and 10,400 Pa for the rectangular specimen. Damage observations show that no tearing or rupture failures are observed for the CWSSR system. The investigation results contribute the most to the safe design of the ZNDS Center and are expected to provide guidelines for future applications of the CWSSR system.

ABSTRACT: In this paper, a size-dependent three-dimensional (3D) nonlinear weak formulation is provided to examine the nonlinear primary resonance problem for functionally graded rectangular small-scale plates. The small-scale factors are taken into formulation by choosing the Mindlin's strain gradient theory (SGT). According to the variational differential quadrature (VDQ) method, first, the displacement field, nonlinear strain-displacement and constitutive relations as well as the potential and kinetic energies are expressed as the vector and matrix forms. Then, by applying the discretized form of differential operators obtained via the generalized differential quadrature (GDQ) method, the discretized form of aforementioned relations is achieved. Finally, Hamilton's principle is employed to access the weak form of 3D nonlinear governing equations of thick rectangular small-scale plates. The achieved formulation is solved via a multi-step numerical technique to address the size-dependent nonlinear primary resonance of considered system under the harmonic lateral force. In addition to reducing the run time, computational effort and CPU usage, the feature of proposed weak form formulation is that one can employ it in other solution approaches such as finite element method. Also, the use of this formulation provides the possibility of recovering models on the basis of other types of size-dependent theories such as modified strain gradient and modified couple stress theories (MSGT and MCST). In the numerical results, the effects of boundary conditions, small-scale parameter, material index and geometry are examined.

ABSTRACT: The objective of this work is to report a careful experimental investigation, planned at the University of Lisbon and carried out at The University of Hong Kong, concerning the behaviour and ultimate strength of cold-formed steel web-flange-stiffened (WFSLC) and web-stiffened (WSLC) lipped channel columns undergoing local-distortional (L-D) interaction. It involves 31 specimens (16 WFSLC+ 15 WSLC), brake-pressed from high-strength zinc-coated grades G450, G500 and G550 structural steel sheets, exhibiting critical distortional-to-local buckling load ratios ranging between 0.75 and 1.88. The column geometries were carefully selected to enable testing fixed-ended columns undergoing true L-D interaction and secondary distortional-bifurcation L-D interaction (ensuring evidence of the latter required selecting rather slender columns) – all tested specimens exhibited the expected L-D interactive failures. The specimen material properties were obtained from tensile coupon tests and their initial geometrical imperfections were measured prior to testing. The experimental results presented and discussed consist of column (i) load-displacement equilibrium paths, (ii) photos evidencing the evolution of the column deformed configurations along those paths (including the failure mode) and (iii) failure loads. Finally, the experimental failure load data obtained are compared with their estimates provided by the currently codified DSM design approaches for columns failing in L and D modes, showing their inadequacy to handle L-D interactive failures – the fresh light shed by this comparison will contribute to the timely codification, in the near future, of a DSM design procedure for columns affected by L-D interaction.

ABSTRACT: In this paper, a novel multi-cell tubal structure with randomized cell sizes is proposed to enhance the energy absorption of the conventional square tubes by utilizing the random nature of Voronoi tessellations. Experiments were conducted to develop and validate finite element models. The crashworthiness of these tubes was demonstrated by applying axial and bending loads using the finite element method. The proposed multi-cell tubal structures exhibit a progressive and stable deformation with the formation of folds in the axial loading case and a local and global deformation for the lateral bending case. The peak crushing force (PCF) and specific energy absorption (SEA) of the proposed multi-cell tubal structures were found to be better than the regular multi-cell square tubes with equal cell sizes when subjected to axial loads. When subjected to lateral bending load, the proposed multi-cell tubal structures have a better PCF while the regular multi-cell square tubes have a better SEA. An optimization problem was formulated to enhance the crashworthiness of the structures. The objective functions were derived using meta-models to speed off the search for optimal structures. The axial crushing and lateral bending cases were optimized separately and combined. Multi-objective particle swarm optimization (MOPSO) was employed to solve the optimization problems. The optimal tubal structures have a crushing efficiency of 87.1% and 85.6% for axial and bending loads, respectively.

ABSTRACT: This paper is devoted to investigate the lateral-torsional buckling (LTB) of hybrid corrugated web girders (CWGs) built up from flanges with a yield stress of 690 MPa, which has been used in bridge construction worldwide. The hybrid girders have been utilised to provide a cost-effective solution because of the high material cost of S690. This investigation has been based on the finite element (FE) modelling by using ABAQUUS program. Accordingly, material modelling of S690 has been verified by considering recent experimental tests in the literature. Then, the accuracy of the current FE models of the CWGs has additionally been checked successfully. Parametric study has been carried out on simply-supported girders, for bridge construction, considering mainly the influences of the hybrid ratio and corrugation dimensions on the behaviour of the CWGs built up from HSSs. A limiting slenderness ratio for the inelastic LTB of 2.3 has been found, where more slender girders would not benefit from using such HSS material. Additionally, the strengths of the girders have been compared with EC3 design model, which has been found to provide highly conservative predictions for the current girders. Consequently, a new design model has been suggested. This suggested bending strength is generally found to provide accurate predictions for the hybrid CWGs built up from flanges.
of S690 HSS; especially for girders failing inelastically. Finally, several comparisons have been provided that might aid the structural engineers in designing efficient hybrid cross-sections in the future.

ABSTRACT: A symplectic wave-based method is applied to the vibro-acoustic problems of submerged ring-stiffened cylindrical shells, accounting for the effects of hydrostatic pressure and acoustic-structure interaction. The symplectic wave-based method combines the symplectic state space theory with the traditional wave propagation approach, and shows the characteristics of high precision and high numerical stability. However, this method is only applied to the vibration analysis of relatively simple and geometrically regular structures before. In this paper, the method is extended to the acoustic vibration analysis of general ring-stiffened cylindrical shells, in which numerical integration strategies are adopted to deal with unknown acoustic-structure coupling terms, finally a complete coupled vibro-acoustic analysis is realized. A further quantitative investigation clearly reveals the effects of hydrostatic pressure on the vibration and acoustic responses. Compared with the existing methods, the present method shows better convergence and accuracy properties, especially when the stiffening rings are dense. It is also shown that hydrostatic pressure cannot be ignored in the acoustic radiation analysis if the low-frequency near-field acoustic pressure is concerned, otherwise, it can be ignored.

ABSTRACT: Multi-cell tubes are widely used as energy-absorption components in transportation field due to its high energy absorption capacity and good weight efficiency. However, with the increase of vehicle speed, people have high requirements for safety, and therefore, the crashworthiness performance of multi-cell tubes should be further improved. To this end, we proposed a new type of multi-cell circumferentially corrugated square tubes (CCSTs) by implementing multi-corrugation on the cross sections of the traditional multi-cell square tubes (STs). Experimental, numerical and theoretical methods were adopted to investigate the crushing mechanics of the multi-cell CCSTs. The results showed that the crashworthiness performance of the multi-cell CCSTs was significantly superior to that of the multi-cell STs. In addition, parametric study was performed to reveal the effects of geometric parameters on the crashworthiness characteristics. In conclusion, this work is of positive significance for improving the level of crashworthiness of thin-walled tubes, and this structural design method can also be used for other traditional structures.

ABSTRACT: Experiments are performed in this study to investigate the influence of impact locations on the damage and compression behavior of stiffened composite panels with a single L-shaped stiffener. After the application of low-velocity impact to the flange tip or web from the outboard side with the same energy level, significant differences among the damage types in specimens are observed. The flange tip impact induces complex damage types including ply fracture, splitting, delamination, and stiffener/skin interface debonding. The stiffness discontinuity results in the extensive propagation of delamination along the longitudinal direction. In contrast, the web impact damage is minimal because of the web's high stiffness. The results of compression after impact reveal that these two types of damage lead to considerable differences in compression behavior. The severe damage caused by the former leads to a considerable reduction in buckling load; however, the
buckling deformation drives the rapid propagation of damage without any constraint. As a result, no distinct post-buckling stage is observed, and the failure load is considerably reduced. On the other hand, the damage caused by the latter weakens the interaction between the stiffener and skin, thereby slightly reducing both buckling and failure loads. Based on these findings, several suggestions on aircraft structure design and inspection are proposed to avoid significant damage and rapid damage propagation.

ABSTRACT: We propose an efficient computational model for predicting the surface wrinkling in axially compressed bi-layer cylindrical shell-substrate composites. To capture the transitions between the wrinkling modes in the far post-buckling regime, we use implicit dynamics. In this context we apply a generalized-α and an energy-decaying time stepping schemes that numerically dissipate in the high frequency range. The other components of the model are a geometrically exact, rotation-less, nonlinear shell finite element for the cylinder and an elastic foundation that represents the substrate. We show that the proposed computational model predicts the wrinkling pattern transition from axisymmetric to diamond-like mode, which is consistent with the numerical and laboratory experiments reported earlier. Furthermore, the results of our computational model show the existence of several diamond-like mode jumps in the post-buckling regime, a result that has not yet been reported for the axially compressed shell-substrate cylinders.

ABSTRACT: In this study, we numerically investigate static and free vibration responses of functionally graded (FG) porous plates with graphene platelets (GPLs) reinforcement using an efficient polygonal finite element method (PFEM). While the bending strain field is approximated through quadratic serendipity shape functions, the shear strain field is calculated by employing Wachspress basis functions. In order to eliminate the shear locking phenomenon, Timoshenko’s beam theory is utilized to determine assumed strain fields on each side of polygonal domain. The present formulation possesses various outstanding features: (a) is valid for triangular, quadrilateral and polygonal elements; (b) can conveniently implement various different plate theories via choosing appropriate transverse shear function; (c) eliminates the shear locking phenomenon; (d) does not increase degrees of freedom (DOFs) per polygonal element despite employing the quadratic serendipity shape functions and (e) obtains more accurate and stable results than those of other PFEMs. Various dispersions of internal pores as well as GPLs into metal matrix through the thickness of plate are examined. The effective material properties varying across the plate's thickness can be estimated by Halpin-Tsai model for Young's modulus and the rule of a mixture for Poisson's ratio and mass density. The effect of several important parameters such as porosity coefficient, weight fraction and dimensions of GPLs, distribution of porosity and GPLs into metal matrix are thoroughly investigated via various numerical examples.

ABSTRACT: Murakami's Zig-Zag Function in conjunction of Green-Lagrange Strain- and Second-Piola Kirchhoff Stress-tensors and Generalized Unified Formulation are introduced for the first time to present a class of Zig-Zag theories for composite structures. Transverse strain effects are retained and modeled, making the
present approach also suitable for thick structures. Each displacement variable is independently represented with user-selected order of expansion. The stress recovery is achieved with a special procedure in which combination of deformation gradient and Second-Piola Kirchhoff transverse stresses are integrated along the thickness of the undeformed geometry. Comparison with available data and commercial codes indicate the effectiveness of the proposed framework for variable kinematics Zig-Zag theories in the presence of large displacements.

ABSTRACT: This paper aims to lighten the weight of concrete-filled steel tubes using wood blocks. Different proportions of wood to concrete were used in a way that wood blocks were substituted with a fraction of concrete in small-scale columns. The behaviour of the composite members was compared with the reference specimens, i.e. fully concrete-filled tubes. Carbon Fibre Reinforced Polymer (CFRP) was also employed as a confining material for some specimens, the effect of which was investigated. The weight reduction that timber provided was evaluated against the axial capacity of each specimen. A new index is introduced to quantify the structural efficiency with a view to evaluating capacity change against the weight. A new parameter is defined in this paper to determine and quantify the transitional response of columns under compression between different peaks loads on load-displacement graphs. This parameter can further help reduce potential risks of failure/collapse at post-peak stages.
A key finding was that the number of timber blocks in specimens with the same volume of timber did not affect the axial capacity, which paves a path for designing timber blocks in multiple numbers. Despite a significant difference between the compression strength of timber and concrete, the capacity reduction provided by timber was not proportionate (was smaller) to the strength difference of the two materials, nor was proportionate to the weight reduction. This disproportion, which can be due to the interaction of all three materials, is structurally desirable especially for the seismic design where the total weight plays a key role. This can be attributed to the usage of stronger and thicker steel acting as a confining material, which is advised for similar structures based on the results of this study.

ABSTRACT: A Kelvin–Voigt based constitutive equation is implemented in Hamilton's framework in order to derive the coupled in-plane/transverse equations governing the motion of a microplate with geometric imperfections, while considering geometric nonlinearities. The Kirchhoff plate theory and the modified couple stress-based theory (MCST) are utilised to obtain the strain and kinetic energies of the imperfect microsystem. Then, the Kelvin–Voigt energy dissipation scheme is employed to derive expressions for the work of the viscous components of the classical and non-classical stress tensors. Frequency-response diagrams are plotted to investigate the nonlinear resonant oscillations of the imperfect viscoelastic microsystem in the presence of geometric imperfections. Numerical simulations revealed that the concurrent presence of geometric imperfections and the nonlinear amplitude-dependent damping mechanism alters the bifurcational behaviour of the viscoelastic microsystem substantially. It is shown that at oscillations of large amplitude, the nonlinear damping contributions become significant.

ABSTRACT: The main purpose of this research is to obtain analytical formulations for exact calculation of relative post-buckling stiffness of nonlocal graphene sheets. In addition to calculating the post-buckling stiffness reduction, the buckling and initial post-buckling responses of these structures, when they are subjected to end-shortening strain, have also been studied. To investigate these phenomena, a new technique called semi-Galerkin technique is used in which the out-of-plane deflection function is firstly postulated as the only displacement field and then, exact nonlocal stress function is calculated through a complete solution of the von-Karman compatibility equation. Finally, Galerkin’s method is used to solve the unknown parameter considered in the proposed technique. The nano-sheets are modeled as an orthotropic layer with Kirchhoff assumptions and nonlocal differential elasticity theory is employed to achieve the buckling loads and exact relative stiffness values. For in-plane movements of the longitudinal edges of the nano-sheets, two essential and natural boundary conditions are adopted to be “straightly movable” or “freely movable”. The effects of aspect ratio and nonlocal parameter have been studied for each type of boundary conditions and for graphene sheets with different materials. The stress distribution along the length and the width of the nano-sheets is also investigated and discussed by the two local and nonlocal theories and for various values of nonlocal parameter.

ABSTRACT: Thin-walled tubes have been widely used in crashworthiness applications such as automotive and aerospace industries. However, inevitable structural imperfections in the tube wall impose adverse effects on the energy absorption performance of the tube. Here, we have employed a fluid-like and highly compressible material, i.e. liquid nanofoam (LN), as a filler to suppress the negative impact of structural imperfection. The mechanical performance of empty tubes and LN-filled tubes (LNFT) with different dent imperfections has been evaluated by quasi-static uniaxial compression tests. Results show that empty tube is susceptible to structural imperfection, as a v-shaped dent with 1.5 mm depth reduces the energy absorption capacity by about 20%. In contrast, the mechanical performance of LNFT is insensitive to the existence and depth of the dent. The enhanced imperfection insensitivity of LNFT is due to the intimate liquid-solid interaction at the LN filler and the tube wall interface, which effectively suppresses the curvature growth of the dent and the localized folding. The findings provide an efficient approach for designing and engineering thin-walled energy absorption devices that are resilient and of high energy absorption capacity.

ABSTRACT: Honeycomb structure, which presents potential ability in energy absorption and impact resistance, has advantages of simplicity, lightweight, easy manufacturing and designability. In this study, honeycomb structure panel is expanded to cylindrical shell by adopting the rolled-up algorithm and the crushing behaviors of the randomly honeycomb cylindrical shell (RHCS) structures are investigated under axial loading. The influence of geometrical and topological parameters, i.e. the thickness-to-diameter ratio, cell irregularity, relative density on the deformation evolution and energy absorption performance is systematically performed. It is found that the deformation modes of RHCS structures are significantly affected by thickness-to-diameter ratio and cell irregularity. Moreover, the rate-independent, rigid–plastic hardening (R–PH) idealisation with two parameters is adopted to characterize the crushing responses of RHCS structures and the parameters are quantified as power-law relations with respect to relative density. Further, the crushing behaviors of density-graded RHCS structures with continuously varying in density are carried out under different impact velocities. Results indicated that the introduction of density gradients can strongly affect the deformation mode, crushing force and energy absorption performance of density-graded RHCS structures. Combining with analysis of crushing front propagation, the theoretical determination of crushing responses of the density-graded RHCS under different loading rates is presented based on R–PH model. The results of predicted crushing force-time histories of density-graded RHCS structures show versatile agreement with that of finite element values at both impact and support ends. Additionally, the energy absorption capacity that is related to deformation mechanisms of density-graded RHCS structures is investigated.

ABSTRACT: In this study, dynamic response of steel-reinforced concrete-filled circular steel tubular (SRCFST) members was experimentally studied under lateral impact loads. Eighteen SRCFST specimens were prepared and tested by the drop hammer impact test system. Various parameters, namely, cross-section of profiled steel, impact velocity and impact direction for I section profiled steel were considered to examine their influences on the failure mechanism, impact force, impact duration, displacement response and energy absorption. Since the beams may be of different constraints at boundary and the columns are axially loaded, boundary condition and axial load level were also considered. The experimental results show that the energy dissipation ratios ($E_d/E$) of all tested specimens except CIFP2-0 are more than 85% and the maximum energy dissipation ratio reaches 97.5%, indicating SRCFST members can absorb large amounts of input energy. Moreover, the inserted profiled steel can effectively enhance impact resistance while reduce energy absorption. It is also found that the peak value ($F_{\max}$) of impact force is very sensitive to the variation of impact velocity. The plateau value ($F_{\text{ave}}$) of impact force and displacement response are very sensitive to the variation of boundary conditions and axial loads, which can significantly change the lateral flexural stiffness of specimens. Given the same impact energy input, SRCFST members with cruciform section profiled steel under fixed-fixed boundary conditions exhibit the best impact resistance performance with the lowest mid-span displacement.

Seyyed Morteza Fatemi Moghaddam and Habib Ahmadi (Faculty of Mechanical Engineering, Shahrood University of Technology, Shahrood, Iran), “Active vibration control of truncated conical shell under harmonic excitation using piezoelectric actuator”, Thin-Walled Structures, Article 106642, Vol. 151, June 2020, https://doi.org/10.1016/j.tws.2020.106642

ABSTRACT: In this study, active vibration control of an FGM truncated conical shell, subjected to the harmonic excitation, is investigated via a semi-analytical method. The governing equations of truncated conical shells in conjunction with piezoelectric layers are derived using Donnell shell theory and von Karman's non-linearity. Then, the dynamic equation of the system is discretized using Galerkin method to obtain the ordinary differential equation of system. Using the semi-analytical method by means of perturbation theory, the frequency response of superharmonic and sub-harmonic analysis of the system is performed. Then, using the piezoelectric smart materials, the active vibration control for the truncated conical shell is investigated and frequency-amplitude functions are analyzed for the superharmonic and subharmonic resonances. The results present the influence of excitation amplitude and cone vertex angle on the frequency-amplitude response and in specific the effect of different control gain coefficients on the system's vibration behavior. Finally, the performance of active control strategy is investigated by means of the time response of system equipped with piezoelectric layers for different types of the FG distribution in thickness direction.

ABSTRACT: This research investigates the effect of using lightweight foam rubberised concrete as an infill material for double-skinned profiled composite panels under pure shear load through experimental and analytical modelling. Three concrete mixes were used as infill materials in this study: one control foam concrete (FC), and two foam rubberised concrete (FRC) with rubber contents of 8.5% and 17% by total mix volume. The pure shear behaviours of the profiled concrete and profiled steel-concrete composite panels were investigated by
testing nine small-scale square panels. Three profiled concrete panels and three profiled steel-concrete composite panels were tested under monotonic pure shear load. In addition, three profiled steel-concrete composite panels were tested under repeated cyclic pure shear load. The monotonic test results showed comparable ultimate loads for both FRC and FC panels. Moreover, the FRC panels experienced a higher number of cracks and higher ductility. The cyclic shearing behaviour of FRC composite panels with 8.5% and 17% rubber contents outperformed the FC panels through increased capacities of about 10.3% and 8%, respectively. The increase in ductility of FRC panels with 8.5% and 17% rubber contents over that of FC panels was about 19.5% and 2.4%, respectively. The cumulative energy dissipation for FRC panels also showed a distinct increase over that of FC panels.

ABSTRACT: To study the effect of corrosion on the bearing capacity of compression-bending steel members, especially the local buckling behaviors, six H-shaped Q345 steel short columns with different corrosion degrees were designed. The outdoor accelerated corrosion test for up to 2 years, monotonic tensile test of standard specimens and eccentric compression test of steel columns were carried out, respectively. The volume loss ratio was used to evaluate the corrosion degree of each specimen. The relationships between failure mode, bearing capacity and deformation behavior to corrosion degree were analyzed. In addition, based on the experimental result, the interactive modeling was carried out by the software Geomagic Studio and ABAQUS, and then the deterioration laws of the bearing capacity of corroded H-section compression-bending steel members under the real corroded surface was also studied. The results showed that the bearing capacity of H-section compression-bending steel member decreased gradually with the increase of corrosion degree, and the yield load, ultimate load and buckling load of the most seriously corroded specimen PY-6 decreased by 22.8%, 23.4% and 33.3%, respectively. Corrosion changed the failure modes of the specimens and gradually decreased the half-wavelength of local buckling, which weakened the plastic deformation capability of specimens, and leaded to the transformation of steel members from strength failure to stability failure. Finally, the novel method considering the corrosion surface morphology was verified by comparing the finite element solutions to the experimental result. It was found the rough surface of the corroded specimens caused the uneven stress distribution and stress concentration. The location of maximum stress was located in the most severely corroded area, which leaded to the failure of the specimens.

ABSTRACT: Unified formulae of elastic critical distortional buckling load and unified DSM expressions for columns undergoing pure distortional buckling, are proposed in this study for both pinned-end and fixed-end columns with a C/Z/hat sections. The normal stress distribution of pre-buckling and post-buckling for C-section columns undergoing distortional buckling is presented based on theoretical analysis and literature review. The basic purpose of the DSM expressions is to express the strength problem as a stability problem to determine the ultimate strength of columns experiencing pure distortional buckling. To understand the effects of both pinned-end and fixed-end conditions in the columns undergoing pure distortional buckling, the effective length factor of flexural buckling about the strong axis of a cross-section, is introduced into elastic distortional buckling load formulae and the DSM expressions. Numerical results computed by computer software (CUFSM), along with numerical and experimental results in literature reviews are used to assess the accuracy of the proposed formulae. It is shown that the proposed formulae are accurate and universal.

ABSTRACT: The analysis of internal resonances in continuous structural systems is one of the main research areas in the field of nonlinear dynamics. Internal resonances enable the transfer of energy between the related vibration modes, usually leading to new phenomena that have a profound influence on nonlinear oscillations, bifurcations and dynamic instabilities. Shells of revolution usually exhibit internal resonances due to their inherent circumferential symmetry and dense frequency spectrum in the lower frequency range, which may lead not only to simple internal resonances but also to multiple internal resonances. In this work, the nonlinear response of an imperfect circular cylindrical shell, simply supported at the edges, to harmonic excitation is studied. Geometries that have two modes with n and n+1 circumferential waves, corresponding to the lowest natural frequency, are identified. These two modes are driven to resonance, with each being in one-to-one internal resonance with its companion mode, thus leading to a possible 1:1:1:1 internal resonance, a topic rarely investigated in the technical literature. The investigation of internal resonances in continuous systems is usually conducted using low-dimensional discrete models. Here, using a perturbation procedure, a consistent modal expansion is derived for an arbitrary number of interacting modes, leading to reliable low-dimensional models. Using the discrete models derived in this way, the shell nonlinear dynamics is explored by using bifurcation diagrams of the Poincaré map, continuation techniques and the Floquet stability criterion. The importance of internal resonances to the nonlinear vibrations and instabilities of the shell is clarified. It is well known that small geometric imperfections in the order of the shell thickness have a strong influence on the buckling and post buckling behavior of a thin-walled shell. However, their influence on internal resonances, dynamic instability and energy transfer is largely unknown. Thus, a detailed parametric analysis that considers different types of modal imperfection is conducted in the present work, and the influence of such imperfections on the activation of energy exchanges between the modes involved is analyzed. The results confirm that the form and magnitude of initial geometric imperfections have a profound influence on the results, enabling or preventing the transfer of energy among the resonant modes being considered.

ABSTRACT: Stiffened shells are widely used in aerospace structures such as launch vehicles and aircraft wings. This paper presents a novel two-scale topology optimization method to design the innovative grid-stiffened pattern for maximizing the critical buckling load of thin-walled cylindrical shells. On the micro-scale, the asymptotic homogenization method is employed to calculate the general stiffness coefficients of the cell. On the macro-scale, the maximum critical buckling load is set as the objective to drive the topology optimization on the micro-scale. Besides, the repeated eigenvalues are considered both in the sensitivity analysis of buckling loads and the optimization solver with a sub-problem based on the Method of Moving Asymptotes (MMA). Through the optimization, we can obtain the optimal configuration of the grid-stiffened cell. In this paper, an illustrative example of the grid-stiffened cylindrical shell for maximizing the critical buckling load is carried out to validate the effectiveness of the proposed optimization method. In comparison to the optimal orthogrid shell, the critical buckling load with the optimal pattern obtained by the proposed optimization method have a dramatically increase of 21.7%. It can be concluded that the proposed method has huge potential to design the configuration of the grid-stiffened cell of cylindrical shells.

ABSTRACT: In this paper, based on the strain gradient theory, a size-dependent porous axially functional gradient (AFG) flexoelectric Euler-Bernoulli nanobeam model is developed. A modified power-law formula incorporating porosity volume fraction is presented to describe material properties of porous AFG nanobeam, and two typical porosity distributions patterns are considered. The generalized differential quadrature method is employed to discretize governing equations into a series of linear algebraic equations, so that the static bending deflections and free vibration frequencies are calculated conveniently for various boundary conditions. The credibility of the present mathematical formulation and the associated numerical solution are validated by comparing the results in previous literatures. Parametric studies are performed to illustrate the effects of the flexoelectricity, material length scale parameters, functionally graded index, porosity volume fraction, porosity distribution patterns on the static bending and free vibration behaviors of porous AFG flexoelectric nanobeam. The numerical results may provide support for the application of porous AFG flexoelectric nanobeam in Nano-electro-mechanical system.

ABSTRACT: A novel lightweight sandwich construction with square honeycomb-corrugation hybrid core (SHCH) was fabricated by honeycomb-corrugation assembly and vacuum brazing. The out-of-plane quasi-static compression behavior of the hybrid structures was explored in detail by experimental measurement, numerical calculation and theoretical prediction. The proposed brazed structures in high density region are found still to have strength and energy absorption capacity significantly greater than the sum of those of empty corrugated sandwich and square honeycomb-cored sandwich. In addition, the compressive strengths of the proposed square honeycomb–corrugation hybrid cores exhibit obvious superiority over those of competing core topologies in the high-density region.

ABSTRACT: In this study, the dynamic characteristics (i.e. natural frequencies and associated mode shapes) of a partially filled horizontal cylindrical shell are investigated experimentally and by an isogeometric finite element-boundary element method. The proposed numerical procedure is divided into two parts. In the first part, the dynamic characteristics of the cylindrical shell under in-vacuo conditions are obtained by the isogeometric finite element method (IGAFEM) based on a linear Kirchhoff-Love shell formulation. In the second part, the fluid-structure interaction effects are calculated in terms of generalized added mass coefficients by using the isogeometric boundary element method (IGABEM), assuming that the structure vibrates in its in-vacuo principle mode shapes. By adopting the linear hydroelasticity theory, it is assumed that the fluid flow is ideal, i.e., an incompressible flow and inviscid fluid. In order to show the versatility of the numerical method, the results are compared with those obtained by the conducted experiments. Relevant numerical challenges in the hydroelastic vibration analysis are highlighted and it is shown that the numerical predictions and experimental results are in good agreement.

ABSTRACT: A comprehensive experimental and numerical investigation of the interactive buckling behavior of welded I-section steel columns was undertaken. The experimental program employed 16 welded I-section columns made of Q235B or Q345B steel and included material tensile coupon tests, column tests, and initial geometric imperfection measurements. The specimens were selected to cover a wide range of width-to-thickness ratios and slendernesses. Comparisons between the test results and current specifications Eurocode 3 and ANSI/AISC 360–16 were presented, and the accuracy of the specifications was evaluated. In conjunction with the experimental program, a finite element (FE) model was used to replicate the tests. FE models considering initial imperfections and material nonlinearity were established and the reliability of the modeling methodology was verified by test results. On the basis of the calculation results, a design proposal for both normal and high strength steel is presented. Comparisons of the FE results with the predictions by the design provisions revealed that the new design proposal is more accurate than the current specifications.

ABSTRACT: An experimental and numerical study was conducted aiming to understand the flexural-torsional buckling phenomenon in angle fixed end columns with equal compact legs made of hot rolled austenitic stainless steel 304. The experimental programme was divided into four steps: cross-sections and column length selection; measurement of the columns initial geometric imperfections, i.e., local (cross-section rotation) and global (major and minor-axis bending); material characterisation in terms of its response under compression and tension stresses; development of the tests aiming to determine: failure modes, equilibrium paths and the columns’ ultimate loads. A numerical investigation was also carried out, where the finite element models were validated against the performed experiments, to expand the experimental results to cover additional cross-sections and column lengths. This was followed by an assessment of two design methods for angle fixed ends columns with compact equal legs: Eurocode 3 – part 1.4, specific for the stainless steel materials, and a design procedure based on the direct strength method developed by Dinis et al. for carbon steel materials. These two methods proved not to be reliable for the column ultimate loads prediction and motivated the development of two novel design procedures based on the Eurocode 3 – part 1.4 methodology. These two novel design methods provided more consistent results when the flexural-torsional buckling ultimate limit state controls the structural design of austenitic stainless steel equal leg angle.

ABSTRACT: This paper aims to develop a practical artificial neural network tool for predicting the axial compression capacity of circular concrete-filled steel tube columns with ultra-high-strength concrete. For this purpose, a nonlinear finite element analysis of circular concrete-filled steel tube columns with ultra-high-strength concrete was conducted and verified with experiments in the literature. Accordingly, a database of 768 finite element models was generated to use for developing the artificial neural network models. In this regard,
the column length, the diameter of steel tube, the thickness of steel tube, yield and ultimate strength of steel tube, and compressive strength of concrete were considered as the input variables while the axial compression capacity was considered as an output variable. The performance of the proposed artificial neural network model was compared with the current structural design codes including AS/NZS 5100.6, Eurocode 4, AISC, and GB 50936. The comparative study indicated that the proposed artificial neural network model achieved a superior prediction compared to others. Ultimately, a graphical user interface tool was developed based on the proposed artificial neural network model to predict the axial compression capacity of circular concrete-filled steel tube columns with ultra-high-strength concrete for practical engineering design.

ABSTRACT: By combining circular cells and folded plates, this paper establishes a cross-circular honeycomb model. The model has a simple micro-topological structure. Through theoretical analysis and numerical simulation, we derive a semi-empirical equation describing the plateau stresses of cross-circular honeycombs and investigate their in-plane impact behavior. Hence, this paper primarily discusses the effect of gradient arrangement on the deformation mode, plateau stress, and energy absorption capacity of hollow-circular and cross-circular honeycombs with the same relative density at different impact velocities. The study results indicated that the deformation mode of the cross-circular honeycombs exhibited a zero Poisson's ratio, and these honeycombs exhibited a high plateau stress and high capacity for energy absorption. A density graded design could control the dynamic response characteristics of the cross-circular honeycombs within a wider range of impact velocities. Furthermore, the design of the symmetric gradient distribution provided the density graded cross-circular honeycombs with a multi-directional gradient deformation characteristic.

ABSTRACT: Thin-walled cylindrical shells are primary structures in aerospace, marine and civil engineering. A major loading scenario for these imperfection sensitive shells is axial compression. For this load case, there is a critical disagreement between the theoretical and experimental critical load. This difference is mainly contributed due to shape deviations of the shell middle plane which are commonly described as geometric imperfections. However, some deviations between theoretical and experimental buckling loads are sometimes so severe that other imperfection types are possibly to blame.
This article describes experimental and numerical studies on the influence of loading imperfections on the buckling load of thin-walled cylinders. A global loading imperfection was applied by mistake during a buckling test of a thin-walled cylinder which led to a severe buckling load reduction and the corresponding load level was similar to the post-buckling load. Also, a series of experimental studies with localized loading imperfections is described which significantly reduced the buckling load of CFRP cylinders.
The experimental results of this article represent an example for some of the very low buckling knockdown factors from early experimental campaigns and give insights in how to avoid these critical imperfections in experimental buckling campaigns.

Shao-Feng Nie (1), Tian-Hua Zhou (1), Yang Zhang (1) and Bo Liu (2)
In this paper, a new finite element model is developed for nonlinear analysis of thin-walled beams by introducing a high-order interpolation for the warping displacement field to better simulate actual cross-section deformation. It is discovered that, due to the significant coupling between bending and membrane deformations in each wall, it is crucial for a nonlinear thin-walled beam finite element to be capable to describe complex warping displacement distribution over the cross-section. In the geometrically exact beam element model developed, the warping displacement is expressed by using a higher-order interpolation scheme, while the distortion displacements are independently described by using a number of cross-section in-plane deformation modes. Numerical results are presented to demonstrate the effectiveness of the proposed model and investigate possible impacts of interpolation schemes for the warping displacement distribution on the solution accuracy under different problem settings. The results show that with an appropriate high-order warping displacement interpolation scheme, the proposed beam model can produce very accurate results even in the case of small wall thickness, outperforming many of the existing models. It is therefore concluded that special attention is needed on the warping displacement field for a finite element model to accurately simulate the cross-section distortional deformation of thin-walled beams.

ABSTRACT: Cold-formed thin-walled steel members are commonly subjected to initial imperfection, which will greatly affect their load-carrying capacity. In this study, the load-carrying capacity and imperfection sensitivity of fixed-ended cold-formed steel web-stiffened lipped channel columns subjected to local-distortional (L-D) interactive failure (including secondary local bifurcation interaction (SLI), true L-D interaction (TI) and secondary distortional bifurcation interaction (SDI)) are investigated. A new imperfection simulation method combining finite element analysis (FEA) with the constrained finite strip method (cFSM) was firstly proposed, and then validated using experimental data from literatures. Next, 224 geometries of columns experiencing L-D interactive failure were chosen by the cFSM and their load-carrying capacity under normal state $P_{\text{norm}}$ (with unavoidable minor initial imperfection) and those under imperfect state $P_{\text{imperfect}}$ (with various imperfections) were respectively obtained using FEA. The most unfavorable imperfection patterns for L-D interactive failure were summarized by comparing the $P_{\text{norm}}$ and $P_{\text{imperfect}}$ of the members. Furthermore, the quality of the DSM-based design approaches for L-D interactive failure were evaluated by comparing $P_{\text{norm}}$ with the failure load predictions of the selected columns provided by these design approaches.

ABSTRACT: The flexural-torsional buckling response and design of stainless steel I-section beam-columns are investigated in this paper. First, a series of laboratory tests on laser-welded stainless steel I-section beam-columns susceptible to flexural-torsional buckling is presented. The results obtained are supplemented by further data generated by means of numerical parametric studies on both conventionally arc-welded and laser-welded stainless steel members covering a wide range of member slenderness and combinations of loading. Existing provisions for the design of welded stainless steel I-section elements against flexural-torsional buckling are then assessed and found to require improvement. Finally, new formulae for the design of stainless steel I-section beam-columns susceptible to flexural-torsional buckling are proposed. The new proposals yield improved accuracy and consistency over existing provisions and their suitability for inclusion in the upcoming version of the European structural stainless steel design code EN 1993-1-4 is confirmed by reliability analysis in accordance with EN 1990.

Guangyong Sun, Xiao Guo, Shunfeng Li, Dong Ruan and Qing Li, “Comparative study on aluminum/GFRP/CFRP tubes for oblique lateral crushing”, Thin-Walled Structures, Article 106420, Vol. 152, July 2020, https://doi.org/10.1016/j.tws.2019.106420

ABSTRACT: Thin-walled composite structures are increasingly used in vehicles attributed to their lightweight and high energy-absorbing capacity. However, understanding crushing behavior of tubal structures made of different materials for lateral impact loading from different directions is fairly limited, which restricts their further applications. This study aimed to investigate the oblique lateral crashworthy characteristics of thin-walled circular tubes with aluminum, glass fiber reinforced polymer (GFRP) and carbon fiber reinforced polymer (CFRP) materials by experimental, numerical and analytical methods. Thin-walled tubes were considered to bear the combined lateral compression and shear loading radially through two parallel rigid platens from the oblique angles of 0°, 10°, 20° and 30° to the horizontal direction, respectively. The effects of loading angles on crushing process, failure modes and crashworthiness indicators were quantified. Similar deformation patterns of each type of the tubes can be observed under these different loading angles, where frictional shear was found to be of limited effect on the deformation mode. With increase in loading angle, initial crushing force decreased, also the energy absorption of GFRP tube decreased whilst those of aluminum and CFRP tubes increased as seen from a prolonged process in the energy absorption-displacement curve. The specific energy absorption (SEA) of the aluminum, GFRP and CFRP tubes ranged from 2.36 to 2.62 J/g, 1.1 to 0.88 J/g and 0.79–0.96 J/g, respectively; and their corresponding crushing force efficiencies (CFE) ranged
Further numerical investigation on the composite parts with unsymmetrical ply layups shows FEA for the curved composite parts with symmetrical ply layup cured on a wound carbon epoxy tube. The proposed analytical model is extended to investigate the cure behavior of multilayered curved composite parts. The viscoelastic effects on the residual stresses and spring-in angles of thin-walled curved composite parts during curing. The proposed model is first established to describe the viscoelastic mechanical behavior of an unidirectional curved composite layer based on the viscoelastic constitutive model with N+1 Maxwell elements. The explicit closed-form solution is obtained by a new iterative solution strategy. Then, the analytical model is extended to investigate the cure behavior of multilayered curved composite parts. The viscoelastic effects on the residual stresses and spring-in due to tangential and radial thermal-chemical expansion are separately considered to aid in understanding of their individual influence. The analytical results show good agreements with experimental data in literature and numerically predicted results by viscoelastic FEA for the curved composite parts with symmetrical ply layup cured on a wound carbon epoxy tube. Further numerical investigation on the composite parts with unsymmetrical ply layups shows that the
viscoelastic effects on the spring-in angles are closely related to the ply layups and the thickness of composite parts and have different responses for those due to tangential and radial effects.

ABSTRACT: The compressive behaviour of hot-finished circular hollow section (CHS) steel members in fire is investigated in this paper through numerical modelling. CHS members with high-strength steel grades of S690 and S460 are taken into consideration in addition to those made up of normal-strength grades S355, S275 and S235. Numerical models of CHS structural steel members able to replicate their response in fire are validated. Using the validated finite element models, extensive parametric studies are carried out for the purpose of exploring a broad range of factors influencing the cross-section and member buckling response of CHS steel members under axial compression at elevated temperatures. The accuracy and safety of the design recommendations provided in the European structural steel fire design standard EN 1993-1-2 for the determination of the axial compression resistances of CHS steel members in fire are assessed. New design methods able to provide accurate and safe estimations of the cross-section axial compression resistances and flexural buckling resistances of CHS steel members at elevated temperatures are proposed. The higher accuracy, reliability and safety of the proposed design methods relative to the existing design provisions in EN 1993-1-2 are illustrated.

ABSTRACT: In this paper, a numerical model for shear links was firstly established and carefully validated, and the cyclic web buckling behavior were also discussed with comparison to experimental results. On this basis, firstly, the influence of boundary conditions was explored. The influence of axial displacement constraint on cyclic buckling and plastic overstrength was discussed, and a theoretical plastic overstrength factor considering axial displacement constraint was proposed. In addition, the influence of axial forces on cyclic buckling and plastic overstrength was discussed, and the limited range of axial forces on shear links was recommended. Afterwards, the influence of various parameters on cyclic web buckling was analyzed and discussed, and a theoretical prediction approach for cyclic buckling angle was proposed, which was applicable to shear links with or without stiffeners. Also, the influence of parameters on plastic overstrength was analyzed and discussed, and the theoretical model of the relationship between plastic overstrength and displacement angle was proposed for shear links with or without stiffeners. Finally, based on the works above, a simplified theoretical model to predict the relationship between shear force and displacement angle was proposed, with consideration of cyclic buckling. The experimental validations confirmed it had good accuracy.

ABSTRACT: Hexagonal thin-walled structures are widely used in protective engineering and the precise prediction of their collapse behavior is very important for their crashworthiness design. In this paper, a precise theoretical model is proposed to predict the collapse behavior of hexagonal tubes under lateral compression. The rigid-linear strain hardening constitutive relation is adopted for the hexagonal tubes. A deep insight into the in-plane deformation mechanism of hexagonal tubes is presented. Comparisons of the present model with the finite element analysis, existing experiments, and conventional rigid-perfectly plastic model are conducted. It is demonstrated that the present model shows a good agreement with both the numerical simulations and the experiments. The influences of strain hardening and tube wall thicknesses on the crushing behavior are discussed. Based on the theoretical analyses, a nearly constant force-displacement plateau is obtained by selecting appropriate strain hardening modulus and wall thickness of the hexagonal tubes. The present study will pave an effective way to clearly understand the large plastic deformation of thin-walled structures with various cross sections.
Bending actions.

Accuracy of predicting the midspan load capacity of channel sections under combined web crippling and bending action was undertaken to investigate the combined web crippling and bending interaction behaviour of cold-formed steel channel sections used as bearers in floor systems with fastened supports. A numerical study was therefore undertaken to investigate the combined web crippling-bending interaction behaviour of unlifted channel sections used as bearers in floor systems with fastened supports. Web crippling finite element models developed and validated by the authors in a recent study were extended to investigate the behaviour of unlifted channels under combined action of web crippling and bending while new finite element models were developed for bending and validated using available experimental results. All three types of finite element models were used in a detailed parametric study to obtain the capacities of 12 unlifted channel sections made of G250 and G450 steels under pure and combined web crippling and bending actions. Comparison of the combined web crippling and bending capacities obtained from finite element analyses with the interaction equations in three cold-formed steel design standards, AISI S100, AS/NZS 4600 and Eurocode 3 Part 1.3, showed that the current design equations are accurate for 50 mm bearing length. However, they can also be used to predict the combined web crippling-bending capacities conservatively for bearing lengths of 100 and 150 mm. A new design equation with a suitable capacity reduction factor was then proposed to improve the accuracy of predicting the mid-span load capacity of channel sections subject to combined web crippling and bending actions.

ABSTRACT: The flexural buckling behaviour and residual strengths of stainless steel circular hollow section (CHS) columns after exposure to fire were studied, based on a thorough experimental and numerical modelling programme, and reported in this paper. The experimental programme was performed on three series of specimens, and each series contained five geometrically identical specimens, with one unheated and the other four heated to different levels of elevated temperatures (namely 300 °C, 600 °C, 800 °C and 1000 °C). The detailed heating, soaking and cooling processes, material testing and pin-ended column tests were described, with the derived key experimental results fully presented. The testing programme was supplemented by a numerical modelling programme, including a validation study where finite element models were developed and validated against the test results, and a parametric study where the validated finite element models were employed to derive further numerical results over an extended range of cross-section dimensions and member lengths. Due to the absence of existing design codes for stainless steel structures after exposure to fire, the codified design provisions for stainless steel CHS columns at ambient temperature, as established in the Europe, America and Australia/New Zealand, were assessed for their applicability to stainless steel CHS columns after exposure to fire, based on the obtained test and numerical data. The assessment results generally revealed that the design buckling curve, as adopted in the European code, and the tangent modulus method, as employed in the American specification, lead to unsafe and scattered design flexural buckling strengths for stainless steel CHS columns after exposure to fire, while the explicit approach, as used in the Australian/New Zealand standard, yields a high level of accuracy and consistency in predicting the post-fire flexural buckling strengths of stainless steel CHS columns.

ABSTRACT: While mechanical properties and material stress-strain response of different families of stainless steel (known as austenitic, duplex and ferritic) are different from each other, current cold-formed stainless steel standards do not generally take into account these differences as they provide single equations for any loading scenario to cover all groups of stainless steel. This may lead to inaccurate results, especially for austenitic steel which is a high performance material increasingly used in modern construction, due to its higher ductility and ultimate-to-yield strength ratio. This research aims to investigate the web bearing performance of cold-formed steel channels fabricated with austenitic stainless steels subject to concentrated transverse forces experimentally and numerically. The experimental programme consists of 16 thick unlipped channel specimens with different internal fillet radius and web depth to thickness ratios. For the numerical investigations, 88 detailed nonlinear quasi-static finite element models are used and validated against experimental data. Complementary parametric investigations are then conducted to ascertain the web bearing strengths in terms of various channel sizes, web thicknesses and internal fillet radius. It is found that the equations proposed by current stainless steel standards are unreliable for austenitic steel as they can lead to significantly un-conservative results (up to 43%) under both one- and two-flange loading scenarios. Other equations suggested in the literature for ferritic stainless steel are also shown to provide overestimated results (up to 34%) for austenitic steel channel sections. Based on the experimental and analytical results from this study, new equations are proposed to estimate the web bearing strength of cold-formed austenitic stainless steel channels and their reliability is demonstrated.

ABSTRACT: This work presents two finite elements for geometric nonlinear analysis of thin-walled laminated composite beams. The element cross-section properties are evaluated through a suitable thin-walled beam theory, yielding a 4x4 constitutive matrix where different couplings between generalized stresses and strains
can be considered. In the local coordinate system, one element named CRL is linearly formulated, while the other element named CRTL incorporates moderate rotations. The element independent corotational approach is used in order to deal with large rotations in 3D space. Numerical experiments, considering different cross-sections and layups, demonstrate the accuracy and effectiveness of the proposed finite elements.

ABSTRACT: Mechanical behaviors of a new foam filled 2D re-entrant hexagonal honeycomb with negative Poisson's ratio under planar compression have been investigated in this paper. Re-entrant hexagonal unit cell specimens were fabricated by aluminum alloy and polyurethane foam. The deformation modes and force-displacement curves of the unit cell specimens under compression were carried out experimentally and numerically, and a good agreement was observed between experimental results and numerical simulation results. Subsequently, mechanical behaviors of foam filled and void re-entrant hexagonal honeycomb under planar compression were observed by numerical simulation. Compared to the void honeycomb, the foam filled honeycomb has a higher specific energy absorption capability due to a higher plateau stress. According to the mechanism of auxetic effect, the re-entrant honeycomb would move inward when subjected to compression along the orthogonal direction, which cause a biaxial compression of the foam and an increasing of stiffness/strength/energy absorption capability. The present investigations provide thorough insight into the strengthened re-entrant hexagonal cellular honeycomb, and could be used in the development of novel light weight smart functional structures.

ABSTRACT: Bridges around the world have utilised individually the mono-symmetric I-section corrugated web girders and the high-strength steel materials (HSSs). However, based on open database, there has not been any investigation in the literature exploring the mono-symmetric corrugated web bridge girders (CWBGs) constructed from HSSs. The paper is, therefore, devoted to numerically explore the global buckling of such girders built up from S460, which has extensively been used in bridge construction globally. This has been made based on finite element models (FEMs) developed by ABAQUS programme. Note that this paper merely considers girders having unequal flanges, but are symmetrical with regard to their minor axis, and their wider flanges are always deemed under compression. The validity of the current FEMs has not only depended on the previous experience of the authors, but also on the comparison between the elastic critical buckling moments and the available prediction methods. Additionally, experimental test results of flat-webbed girders have been considered in the validation. Parametric study has been carried out on simply supported girders considering mainly the influences of the mono-symmetry ratio and corrugation dimensions on the flexural buckling performance of the CWBGs which utilise S460 HSS. Several conclusions have been found that might aid the structural engineers in designing efficient cross-sections in the future. Additionally, the ultimate loads of the current CWBGs have been compared with EC3 specifications, and two design failure modes have been found to take place in present parametric study; the tension flange yielding and the lateral-torsional buckling (LTB) of the compression flange. The results, generally, show that the recommended method by EC3, for equivalent welded sections, is the most suitable in predicting the strengths of the current girders. Though, two modifications have been suggested for EC3 strengths regarding the tension flange yielding design formula and the LTB curve of the girders with depth-to-width ratios ≤2.0. The modified EC3 strength is generally found to provide accurate predictions for the CWBGs which utilise S460 HSS.

ABSTRACT: Use of aluminium sections as primary load bearing members has recently expanded considerably in the building industry. Aluminium as a new constructional material has several advantages in building
structures including corrosion resistance, durability, high strength-to-weight ratio, reduced cost of transportation and ease of erection and fabrication. The popularity of aluminium structures has attracted attention regarding the efficiency and design of many sections, and roll-formed lipped channel beam (LCB) is one of these commonly used sections. However, aluminium LCBs are prone to shear buckling failures due to its increased web slenderness and low elastic modulus compared to steel. Hence an experimental study was conducted to investigate the shear behaviour of LCBs and to verify the current design rules to accurately predict the shear strengths. Shear tests have been conducted using ten different generally available roll-formed aluminium LCBs. The test sections were loaded at mid-span at the shear centre until failure. The results obtained from the tests were then compared with the predictions using the current shear design rules in the Australian/New Zealand standards and Eurocodes for both aluminium structures and cold-formed steel structures as their shear behaviour are quite similar. This paper presents the details and results of this experimental study and comparison with shear design rules based on current design rules.

ABSTRACT: Ultra high performance cementitious composites filled steel tube (UHPCC-FST) column has been widely applied as the load bearing members for long-span bridges, which are the potential bomb explosion attacking targets in terroristic activities. In the authors’ previous work, the residual axial load bearing capacity of UHPCC-FST specimens under contact explosion was investigated experimentally, and this paper further perform the corresponding numerical simulation study. By utilizing the multi-material Arbitrary Lagrange-Euler (ALE) algorithm, Fluid-Structure Interaction (FSI) method, the restart input data method and element erosion algorithm implemented in the finite element (FE) code LS-DYNA, the numerical simulations corresponding to the contact charge explosion and the following axial compression tests are carried out. The damage and failure modes of UHPCC-FST specimen are reproduced and validated by comparing with the experimental data. Furthermore, the related parametric influences, e.g., thickness and strength of steel tube, compressive strength of core concrete and column diameter, on the local blast formed crater depth, the post-blast residual axial load bearing capacity, as well as the corresponding damage index of UHPCC-FST specimen under contact detonation are discussed. The influential degree of above parameters on the residual axial capacity of UHPCC-FST specimen under contact explosion is clarified. The present work can provide helpful references for evaluating the post-blast performance as well as the design of UHPCC-FST specimen under contact explosion.

ABSTRACT: This paper describes the formulation of a thin-walled beam finite element for arbitrary open cross-sections, including doubly-, singly- and non-symmetric cross-sections. The formulation is developed within the co-rotational framework of OpenSees – an open source program available for the simulation of structural and geotechnical systems. The formulation accounts for eccentricity between the shear centre and the centroid of the cross-section, as well as warping. Both elastic and inelastic material behaviour is considered. The stiffness relation for the displacement-based beam element is established based on the Green-Lagrange strain. A local cross-section transformation matrix is derived to relate the end actions with the axial force acting at the centroid to the end actions with the axial force acting at the member axis system. The elastic and inelastic performance of the beam finite element is demonstrated through a series of stability problems comprising doubly-, singly- and non-symmetric sections subjected to compression, bending, and torsion. The buckling and post-buckling behavior predicted by the beam element is shown to be in close agreement with the results of shell finite element models, thereby demonstrating its reliability.

ABSTRACT: In this paper, the free vibration analysis of fuzzy fiber reinforced (FFRC) nanocomposite truncated conical shell is investigated. The FFRC constructional feature is that the uniformly aligned carbon nanotubes (CNTs) are radially grown on the circumferential surfaces of unidirectional carbon fibers. Using a micromechanical model based on the simplified unit cell (SUC) method, the effective material properties of the FFRC conical shells are evaluated. The thin-walled classical shell theory and Hamilton's principle are used to extract the governing equations, and the Ritz method is used to solve the problem. The model predictions are compared with other numerical results available in the literature and the correctness of the proposed theoretical method is attested. Some novel results, including the vibration results of FFRC conical shell accompanied with different combinations of boundary conditions and different material and geometrical properties are presented. The results reveal that the FFRC conical shell vibration behavior is strongly dependent on the material properties, volume fractions of two reinforcements, geometrical characteristics and boundary conditions.

ABSTRACT: The current study experimentally and numerically investigated the ultimate shear loading capacity (USLC) of sinusoidal corrugated web beams (CBWs). The aim of the study was to numerically evaluate USLC for comprehensive practical dimensions of CBWs. In order to validate the numerical simulation strategy, a series of experimental tests on nine girders is performed. A comprehensive parametric study using the nonlinear finite element method then is performed for 160 cases and the effects of various parameters are discussed. The selected dimensions for numerical cases cover the typical range of steel girders in practice. A formula based on the division of areas of the shear buckling modes of sinusoidal CBWs is suggested. The numerical parameters of the proposed relation, representing the web boundary conditions and inelastic effects on shear buckling capacity, are fitted using the parametric study results. The relation was able to predict the UPLC of the numerical cases with an average difference of 10%, which is satisfactory in practice.

ABSTRACT: In this paper, bio-based sandwich panels made of fiber-reinforced polymer (FRP) skins and two types of paper honeycomb core (namely, hollow and foam-filled) with three different thicknesses (namely, 6 mm, 12 mm, and 25 mm) were studied. Flax FRP composites made of a unidirectional plant-based flax fabric and bio-based epoxy resin (30% bio content) were used for the skins. The panels were cut into a total of 36 sandwich beam specimens with the width of 50 mm and tested under four-point bending with two span configurations to characterize the flexural and shear stiffness of the panels. The specimens with foam-filled paper honeycomb cores showed a higher load capacity than those with hollow honeycomb, however their stiffnesses were not fundamentally different. Major non-linearity was observed in the load-deflection and load-strain behavior of the specimens. An analytical model was successfully developed based on the non-linearity of the skins in tension/compression and the core in shear to predict the non-linear behavior of the specimens. A parametric study was performed on different geometrical parameters and it was shown that contribution and bending and shear changes and it can be engineered to achieve desirable strength and stiffness. Overall, the bio-based sandwich panels can be used for interior walls, doors, and furniture in building application with much less impact on the environment in comparison with their synthetic counterparts.

ABSTRACT: Many studies have focused on the topic of vehicle safety, including the study on crashworthiness. In vehicle, a crash box structure is an integral component for ensuring the safety of a car. It serves as an energy-absorbing member, together with the front bumper in case of frontal collision during car accidents. Therefore, special attention has to be given towards this structure in order to have better understanding regarding its mechanism of deformation and absorbing kinetic energy from the collision, as well as on how to obtain good
crashworthy properties from this structure. This study, primarily, is based on extensive literature survey pertaining to the topic of crash box. As the topic of energy-absorbing member in a car is extensive, this review solely focuses on crash box structure. The main motivation of this paper is to summarise the different approaches and aspects of researches performed on car crash box structure to gain comprehensive knowledge regarding the study on crash box.

ABSTRACT: As a sequel to another paper of the authors on welding-induced residual stresses [1], this paper aimed to obtain a direct measurement database of welding-induced initial deformations in a full-scale steel stiffened plate structure and also to study the applicability of computational models to predict them. A full-scale steel stiffened plate structure in association with bottom plate panels of an as-built 1,900 TEU containership was fabricated by exactly the same technology of welding as used in today's shipbuilding industry. The 3D scanner was employed to measure welding-induced initial deformations of the structure. Computational models using the three-dimensional thermo-elastic-plastic finite element method were developed to predict the plate initial deflections. A comparison between direct measurements and numerical predictions was made. Details of direct measurement databases are documented as they are useful to validate the computational models formulated by other researchers.

ABSTRACT: The delamination in curved composite laminates is one of the main defects, especially in aerospace structures. To optimize the design of the delaminated composite panels under compression loading, accurate characterization of the effects of different parameters such as features of the initial defect, the curvature of the laminate, and layup stacking sequence on the post-buckling behavior play a significant role. In this research, after a comprehensive review on the main previous researches, by implementing a Cohesive Zone Model (CZM), the nonlinear post-buckling response of different curved laminated composite panels has been investigated in the presence of various single and multiple delamination growth. To validate the present modeling procedure, the obtained results are compared with the experimental and previous numerical ones. Then, a detailed parametric study is performed on the effects of fiber angle orientation as well as number, size, location and stacking sequence of delaminations with different sizes on the post-buckling behavior of curved laminates with various curvatures. Results show that, in the panels with short length of delamination, an unstable growth occurs. In the flat panel, the amount of this phenomenon and its effects on decreasing the postbuckling load capacity are much more than the curved panel. The obtained results of this study highlight the sensitivity amount of instability behavior of curved composite panels to curvature, layup, and delamination features. The conclusions are essential and beneficial in the stability analysis and damage tolerance design of curved composite laminates, which are commonly used in the aircraft structures.

ABSTRACT: In this article, the nonlinear dynamic response and free vibration of functionally graded porous (FGP) truncated conical panel with piezoelectric actuators in thermal environments are investigated by an analytical method. The panel resting on an elastic foundation which is modeled according to the Winkler–Pasternak theory. The material properties including Young's modulus, shear modulus, and density are assumed
to smoothly through the shell thickness. Three types of porosity distribution across the thickness, namely, symmetric porosity distribution, non-symmetric porosity, and uniform porosity distribution, are considered. Theoretical formulations are presented based on the first-order shear deformation shell theory with a von Karman-Donnell type of kinematic nonlinearity. The non-linear motion equations and resulting equations are derived by using Hamilton's principle, Galerkin's method, and Runge-Kutta method. Lastly, some numerical results are presented to study the effects of shell characteristics, porosity distribution, porosity coefficient, applied actuator voltage, temperature increment and elastic foundations on the nonlinear dynamic response and the natural frequencies of the piezoelectric FGP truncated conical panel.

ABSTRACT: The novel form of hybrid columns, being fiber-reinforced polymer (FRP)-concrete-steel solid columns (FCSSCs), involves the FRP tube and the steel tube as the confining system for the concrete. The buckling of the inner steel in FCSSCs is effectively delayed by the surrounding concrete while the strength of the steel is sufficiently utilized, with it being protected by the outer FRP tube against environmental attacks. A pilot experimental program is conducted to investigate the behavior of axially loaded FCSSCs with an outer polyethylene terephthalate (PET) FRP tube. The experimental results have demonstrated that the axial load carrying capacity of an FCSSC is much larger than the total resistances of the hollow steel tube and the concrete-filled FRP tube. The test FCSSCs possess a monotonically ascending load-strain response with an excellent ductility. The comparisons between the test results and the predictions from existing models demonstrate that one existing model gives satisfactory estimations on the ultimate axial stress and strain of the confined concrete in FCSSCs, while they are incapable to accurately predict stress-strain curves of the confined concrete in FCSSCs.

ABSTRACT: The influences of different shape, size and number of lateral cutouts at various locations on the load-bearing capacity, buckling behaviour and energy absorption ($E_a$) characteristics of aluminium conical frusta under quasi-static axial loading condition were studied from both experimental and numerical procedures. In this regard, 18° semi-apical angled aluminium conical (AC18) frustas were fabricated through the metal spinning process; and circular, square, and trapezoidal shapes of cutouts with required dimensions were introduced at various lateral locations of the frustum. These conical frusta were subjected to quasi-static axial loading at a rate of 2 mm/min using a universal testing machine (UTM), and the corresponding load-deformation characteristics were recorded for axial compression of 50 mm from its original height. In addition to that, similar to experimental studies, Finite Element Analysis (FEA) was performed with conical frusta having various cutouts using ABAQUS® finite element software to study the influence of cutouts on the changes on crashworthiness performance of conical frusta. From both studies, it is observed that the energy absorption capacity of 18° semi-apical angled aluminium conical frusta was found to be decreasing in the range of 3.67%–47.60% according to the shape, size, number and location of cutouts. Further, the load resistance parameters such as first peak load ($P_1$), maximum peak load ($P_m$) and average load ($P_a$) also are found to be decreasing with an increase of cutout size. The change of cutout location from mid-height to three-fourth from the base of the frustum also resulted in a reduction of $E_a$ capacity, regardless of shape, size and number of cutouts. From these studies, it observed that the energy absorption characteristic of conical frusta having circular cutouts are found to be better than the conical frusta having square and trapezoidal cutouts at same locations. It is also observed that the $E_a$ capacity of conical frusta having cutouts was found to be non-linearly decreasing with the linear increase in the number, location, shape and size of cutouts. The specimens with a large-size of cutouts had exhibited large deformation over the cutout region that led to an unstable non-linear global buckling during axial compression. Consequently, their $E_a$ capacity was found to be decreased significantly as compared with the conical frusta with a small size of cutouts. The specimens with the small size of the cutouts exhibited progressive local buckling during axial compression, and they exhibited better energy absorption characteristics as compared with the conical frusta with large size of cutouts.

ABSTRACT: In this study, a new Kirigami corrugated structure is designed. Dash lined cuts across each row of corrugated structures are introduced and then folded inwards. The proposed Kirigami (cut and fold) modification provides extra vertical crushing resistance and constraints between the structure faces. Out-of-plane quasi-static tests are carried out for both conventional corrugated structures and Kirigami corrugated structures made of aluminium thin sheets. The numerical models with imposed imperfections are calibrated with the test data and then used for the dynamic crushing analysis of the structures under various loading rates. Key parameters such as initial peak force, average crushing resistance and energy absorption are compared among the conventional and Kirigami corrugated structures. Significant changes in deformation modes and great enhancement of energy absorption capacity under out-of-plane crushing are shown for the proposed Kirigami corrugated structures as compared to conventional corrugate structures. Furthermore, crushing resistance of the proposed Kirigami corrugated structure is less sensitive to imperfections. Great potential of the proposed Kirigami modification technique on corrugated structures is demonstrated with minimal change in its original manufacturing process but substantial enhancement in energy absorption capacities.

ABSTRACT: This paper deals with wave propagation and vibration of a porous beam embedded via nanocomposite piezoelectric layers. Various patterns of reinforcement of the face sheets by non-uniform graphene nanoplatelets (GPLs) are considered through modified Halpin-Tsai micromechanics model to approximate the Young modulus and Poisson’s ratio of graphene/piezoelectric polymer layers. The sandwich’s face sheets, due to their characteristics, are regarded as sensor and actuator with which the wave velocity and frequency of structure can be controlled and for this reason, a proportional-differential (PD) controller is handled. So as to model the structure much more realistic, the material characteristic of whole system are hypothesized as viscoelastic state according to Kelvin-Voigt model and Kerr viscoelastic foundation is developed which include two springs, two dampers and one shear elements as well. For mathematical modelling of system, refined zigzag theory (RZT) is exercised and using energy method, the motion equations are obtained. Analytical procedure is utilized for solving the governing equations as well as calculating the wave velocity and frequency of the sandwich structure. A precise parametric study is carried out focusing GPLs volume percent and distribution pattern, geometrical parameter of every layer, piezoelectric properties of GPLs, porosity dispersion of the core, exerted voltage and structural damping and their effects on the wave propagation and vibration of system. Results show that increase in the porous coefficient lead to decline in the wave velocity and frequency. In addition, considering the piezoelectric properties of GPLs enhances the wave velocity and frequency of the sandwich structure.

ABSTRACT: The radome structure is composed of the supporting skeleton inside and the stressed skin (membrane) outside. In the previous structural analysis, the stressed skin effect from the envelope is not taken into account, which results in the design of this structure being conservative. To study the effect of the stressed skin on the structure behavior, an experimental study was carried out for a full-scale radome model which has a span of 5.8 m and a height of 4.3 m. A self-designed multi-stage distribution beam loading system was applied to the structure. Therefore, simultaneous loading was realized on the multi-point of the structure. Three load cases—completely covering membranes, partially covering membranes and framework—were considered respectively. Besides, a numerical simulation method for analyzing the overall stability of the radome structure with the consideration of the stressed skin effect is established, which is verified by the test results. Different
from the previous structural analysis that the role of the envelope structure is not considered, the refined finite element model combines beam elements and shell elements to work together, which is a difficulty in the previous research. The mesh size guarantees both the accuracy of results and computational convergence. Considering geometric nonlinearity and material nonlinearity, the whole process stability analysis is carried out by the arc length method, and initial defects are introduced based on the consistent mode imperfection method. Finally, the mechanism of the stressed skin effect is revealed. Both the numerical and experimental study shows that due to the lateral bracing of the stressed skin, the prematurely elastic instability of the members around the weak axis is avoided. The global stability bearing capacity of the structure is significantly improved. As a result, in the design of such radomes, the stressed skin effect should be considered to solve the problem of structural safety and electromagnetic transparency.

ABSTRACT: This is a fundamental study on the nonlinear vibrations considering large amplitude in multi-sized hybrid Nano-composites (MHC) disk (MHCD) relying on nonlinear elastic media and located in an environment with gradually changed temperature feature. Carbon fibers (CF) or carbon nanotubes (CNTs) in the macro or nano sizes respectively are responsible for reinforcing the matrix. For prediction of the efficiency of the properties MHCD's modified Halpin-Tsai theory has been presented. The strain-displacement relation in multi-sized laminated disk's nonlinear dynamics through applying Von Karman nonlinear shell-theory and using third-order-shear-deformation-theory (TSDT) is determined. The energy methods called Hamilton's principle is applied for deriving the motion equations along with Boundary Conditions (BCs), which has ultimately been solved using the perturbation approach (PA) and generalized differential quadrature method (GDQM). At the final stage, the outcomes illustrate that patterns of FG, fibers' various directions, the \( W_{\text{CF}} \) and \( V \), factors, top surface's applied temperature and temperature gradient have considerable impact on the MHCD's nonlinear dynamics. Another important consequence is that, the influences of the \( \theta \), \( W_{\text{CF}} \) and \( V \), amounts on the disk's nonlinear vibrations may be taken into account at the larger amounts of the high deflection element and the negative axial load's impact on the structure's nonlinear dynamics is more extreme. A more general conclusion of this study is that for designing the MHCD should be more attention to the nonlinearity parameter.

ABSTRACT: The prime objective of the present investigation is to predict the shear buckling characteristics of skew nanoplates made of a functionally graded material (FGM) in the presence of surface stress effect. For this purpose, the Gurtin-Murdoch surface theory of elasticity is applied to the higher-order shear deformation plate theory within the framework of the oblique coordinate system. Different types of the homogenization scheme including Reuss model, Voigt model, Mori-Tanaka model, and Hashin-Shtrikman bounds model are taken into consideration in order to extract the effective mechanical properties of FGM skew nanoplates. The Ritz method using Gram-Schmidt shape functions is utilized to obtain the surface elastic-based shear buckling loads of FGM skew nanoplates. It is indicated that by increasing the value of the index associated with the material property gradient, the significance of the surface stress type of size effect on the shear buckling behavior of a FGM skew nanoplate improves. Moreover, by changing the boundary conditions from simply supported ones to clamped ones, the influence of the skew angle on the surface elastic-based shear buckling load of a FGM skew nanoplate increases. Also, it is illustrated that by increasing the width to thickness ratio of a skew nanoplate, the free surface area increases which results in to enhance the effect of surface residual stress on its shear buckling characteristics.

ABSTRACT: The governing differential equations of thin-walled laminated composite curved beams are derived from the principle of virtual displacement. Curvature effect is fully considered, and various displacement components of curved beams are coupled. Buckling behaviors of both the laminated composite I-section vertically (with horizontal web) and horizontally (with vertical web) curved beams are studied. The characteristic displacement function for pinned-pinned curved beams is used to describe both the in-plane buckling and out-of-plane (spatial) buckling behaviors. Closed form solution for buckling analysis of I-section curved beams under compression and bending moment is obtained. Accuracy of the present closed-form solution is verified by comparing with available solutions in the literature and the numerical results of the finite element method usingABAQUS. Then, a practical application of the closed-form solution for I-section composite laminated curved beams is demonstrated, considering the placement of I-section profile, geometry of section, layup in flanges and web, and central angle. Finally, a parametric study is conducted to evaluate the effect of central angle, arc length, radius of curvature, and fiber angle of laminates on buckling behavior of I-section curved beams with either horizontal or vertical web.

ABSTRACT: This paper presents an experimental and theoretical study on the deformation of small diameter aluminum alloy (AA6063T5) circular tubes under lateral impact loading. Seven specimens classified as three groups were investigated by the drop weight test. The patterns and extent of damage between specimens were compared and discussed. Moreover, the experimental results show that the performance of specimens subjected to the lateral impact is significantly affected by the diameter-thickness ratio and impact energy while the impact momentum has little effect. The springback of the global displacement is found to be negatively correlated with the ratio of the impact energy and the diameter-thickness ratio. Afterward, this study develops an analytic solution on the elasto-plastic global displacement of AA6063T5 tubes based on vibration theory. Compared to the experimental results, the elastic solution predicted the global displacement of the aluminum alloy specimens reasonably.

ABSTRACT: Non-linear stability plays an essential role in the design of reticulated shell structures. In order to improve the buckling strength of aluminum alloy spherical shells with gusset joints, this paper proposes a shape optimization method to maximize the non-linear buckling load using a genetic algorithm. The control points of a cubic spline are chosen as the design variables defining the height of the surface. In the non-linear buckling analysis, a linear combination of the symmetric and antisymmetric buckling modes is used as the imperfection mode, and an initial eccentricity is introduced for each member to consider the disadvantageous effect caused by the interaction between the flexural-torsional buckling and global buckling. It is verified in the numerical examples that the proposed method can increase the non-linear buckling load maintaining the smoothness of the surface, while the conventional approach of minimizing the total strain energy is not effective for improving the buckling strength. Finally, the design tables of the parameters of the optimized cubic spline curve are obtained through the parametric analysis considering various load factors and height-to-span ratios, and are verified to be practical and useful under different height of the section, number of rings and support condition.

ABSTRACT: In this paper, a new lamination parameter based method is proposed for the layup optimization of built-up composite laminates with ply drop-offs. The optimization process is divided into two stages. In the first stage, the multilevel optimization feature of the exact strip software VICONOPT MLO is extended to use the lamination parameters and laminate thicknesses of each component panel as design variables to minimize the weight of the whole structure subject to buckling and lamination parameter constraints. For the second stage,
A novel dummy layerwise branch and bound (DLBB) method is proposed to search the manufacturable stacking sequences to find those needed to achieve a blended structure. The method is based on the use of 0°, 90°, +45° and −45° plies and having lamination parameters equivalent to those determined in the first stage. The DLBB method carries out a logical search to circumvent the stochastic search feature of heuristic methods for the determination of stacking sequences. This two-stage method is an extension of a previous highly efficient two-stage method for a single laminate (Liu et al., 2019) [1]. The effectiveness of the presented method is demonstrated through the optimization of a benchmark wing box.

ABSTRACT: This paper aims to study the boundary effects on stretch-induced membrane wrinkling. Towards this end, several typical distributions of tensile loads, that are applied at the short ends of rectangular membranes, are investigated, which produce a system of forces statically equivalent to force and moment. In addition, we explore the relevance of a dimensionless parameter to the buckling loads for these loading cases. By analyzing the critical buckling loads, it is found that small differences in loading conditions lead to critical loads that can differ up to three orders of magnitudes. Besides, the dimensionless parameter is almost constant near bifurcation points independently from boundary conditions. Based on this property, a simple expression is proposed to fast predict the critical load of membrane wrinkling. This paper may provide a simple way to delay or avoid the occurrence of wrinkles by just changing the boundary conditions.

ABSTRACT: In lateral crashes, thin-walled beams may collide with impactors with multifarious shapes and sizes at any position or angle. In addition, the beams are always fixed on other structural components. However, these facts are ignored in the present studies on the bending collapse. This paper aims to investigate the influences of such factors on the transverse bending responses of thin-walled beams. Quasi-static three-point bending tests are conducted first for aluminum square beams loaded at different load angles, positions and spans. The non-linear finite element code LS-DYNA is then utilized to simulate the tests. After validated by the experiment, the finite element model is employed to perform parametric studies to investigate the influences of various factors on collapse responses of thin-walled tubes, and the ranges of the force responses with the variation of these factors are discussed. Results show that the variation of punch shape and size, load position and angle may lead to the switch of deformation modes, while the loading velocity and the height of crash boxes have very small influences on the deformation patterns. Increasing the loading velocity results in a much higher peak force, and fixing the beams on shorter crash boxes achieves a higher force level. In all cases, a sharp punch perpendicularly loaded in the middle of the span controls the lower bound of the crushing force, while the upper bound is governed by the punch approaching the support with small angles. The mean crushing force of the beams can be increased by up to 78% with the variation of the load and boundary factors in the calculations. The findings of this work would be helpful on the crashworthiness design of thin-walled beams under transverse loads.

ABSTRACT: Seismic stability of single-layer dome structures is closely related to both the external seismic ground motions and structural properties. The physical mechanism of seismic instability of single-layer reticulated dome structures is investigated from the perspective of energy, which can take into account both the external excitations and structural properties. First, the energy balance equation is established and the accuracy for calculating each energy component of structures is verified. Then, the energy-based criterion is introduced as a quantitative index for the identification of seismic stability/instability, where the first-passage of the intrinsic energy over the input energy demonstrates the seismic instability of single-layer reticulated dome structures. Besides, some qualitative indices are also employed to further confirm the judgement by the energy-
based criterion. By using the proposed criterion, the critical peak ground acceleration for seismic stability of single-layer reticulated dome structures can be identified by using the incremental dynamic analysis. The energy-based criterion is also validated by comparisons with the B-R criterion. Parametric analyses are implemented to investigate the impacts of different structural parameters on seismic stability and characteristic responses of single-layer dome structures.

ABSTRACT: The paper presents methods of analysis of built-up sections in which the discrete locations of fasteners is accounted for explicitly, rather than by smearing their effect using continuous shear flexibility as in current approaches. By considering fasteners at discrete points, it is possible to analyse the effects of placing additional fasteners at the ends (end fastener groups), to account directly for actual support conditions and to determine the optimum locations of fasteners. The paper first outlines the linear analysis of beams in flexure and introduces the notion of the effective flexural rigidity to account for partial composite actions. Closed form solutions are provided for five load and end support cases to demonstrate the application of the analysis. Next, the paper describes the linear analysis of built-up sections in torsion, considering first uniform torsion followed by non-uniform torsion. Closed form solutions are obtained for the effective torsion rigidity \((EI_\ldots)\) of built-up sections featuring closed loops. A framework is also presented for determining the effective torsion rigidity \((EI_\ldots)\) of open built-up sections in non-uniform torsion. The paper concludes with the analysis of built-up sections subject to flexural buckling. A general variational buckling equation is derived followed by an energy-type method for calculating buckling loads for common end support conditions, including columns supported on flexible end tracks. Closed form solutions are presented for up to seven rows of fasteners longitudinally. While by nature approximate, the solutions are shown to be highly accurate. Comparisons are made between the presented closed form solutions and buckling load predictions obtained using current design provisions.

ABSTRACT: The objective of this study is to investigate the crashworthiness performances of graded lattice structure filled tubes (GLSFTs) under multiple impact loadings. Different graded body-centered cubic

ABSTRACT: Corrosion-induced durability has become a critical issue for aging spatial structures using steel tubes as primary load-carrying structural components. Tremendous efforts have been made in predicting the ultimate strength of steel tubes under axial compression but understanding corrosion-induced buckling remains a challenge due to uncertainty of localized defects. To experimentally investigate the effect of localized corrosion on steel tubes, a modified galvanic method was developed to generate predefined corroded defects at targeted locations. A total of 24 tubes with different slenderness ratios were produced with various localized corroded defects, and then axially compressed to obtain ultimate strengths. Our experiments showed that the galvanic method could efficiently generate localized defects that could change the direction of buckling and significantly lower the ultimate strength of tubes. Further, the corrosion depth has the largest effect on the residual capacity of the tubes among three geometric characteristics of corroded patches. The influence of circumferential corrosion size is greater than that of longitudinal corrosion size due to the deviation of section centroid. From a practical perspective, our experiments indicate that the ultimate strengths of steel tubes can be lower than those estimated by both US and Chinese codes when the localized corrosion ratio exceeds 15%. Thus, the localized corrosion should be checked regularly during the maintenance routine such that buckling-induced failure can be avoided in advance.

ABSTRACT: This paper proposes a numerical and an approximate analytical method for the in-plane non-linear elastic stability of arches under the multi-pattern distributed load. There are six key parts in this paper. Firstly, the approximate analytical solution for funicular axis of arches subjected to the multi-pattern distributed load is derived from the approximations of linear elastic bending moment and horizontal reaction force in the arch end. Secondly, the numerical solution of the in-plane non-linear elastic equilibrium equation is solved by using the shooting method and the bisection method simultaneously. Thirdly, the approximate analytical solutions for the in-plane non-linear elastic equilibrium are derived according to the approximate analytical solution for funicular arch axis obtained from the first part, the simplified strain-displacement expression in Cartesian coordinate system and the virtual work principle. Fourthly, a key parameter is proposed to transform the approximate analytical solutions into the corresponding equations of catenary and parabolic arches. Fifthly, the in-plane non-linear elastic symmetric and asymmetric buckling of arches under the multi-pattern distributed load is derived analytically. Lastly, the in-plane non-linear elastic buckling behaviors of arches subjected to multi-pattern distributed load are deduced based on the obtained analytical solutions. The multi-pattern distributed load with the uniformly distributed load along the span and the uniformly distributed load along the arch is selected as example to verify the proposed method. Comparisons with numerical solutions demonstrate
that the proposed approximate analytical solutions for the funicular arch axis and linear elastic horizontal reaction force agree well with the results of Runge-Kutta method and the proposed approximate buckling predictions have sufficient accuracy compared with the results of finite element method in different rise-to-span ratios, relative slenderness and arch axis parameters.

ABSTRACT: The static stability of clamped-free columns resting on elastic foundation is investigated under a nonconservative subtangential follower force. The higher-order shear deformation beam theories are applied to treat structural instability of a clamped-free rectangular and circular beam resting on Winkler foundation. Based on Engesser's assumption, a single governing equation is derived for divergence instability of Beck cantilever under a subtangential follower force. For different warping shapes of rectangular and circular cross-sections, the critical divergence buckling loads are determined. Static buckling still occurs for a cantilever column subjected to a subtangential follower force with small nonconservativeness parameter and dynamic flutter instability occurs for large nonconservativeness parameter. In a free space, a unified relationship with the Euler buckling loads is given explicitly for the case of a dead load, and the buckling load has an apparent reduction due to shear deformation with different warping of the cross-section. The obtained results further modify the Euler buckling formula to suit for the columns with a broad range of slenderness. Elastic foundation nearly linearly increases the buckling load and a nonconservativeness parameter also raises the divergence buckling load. For shorter columns, the classical buckling loads are significantly overestimated. The effects of slenderness, warping shapes, nonconservativeness parameter, and spring stiffness coefficient are analyzed.

ABSTRACT: The present paper reports experimental and numerical studies of the minor-axis flexural buckling behaviour and resistances of welded I-section columns made of a newly developed grade EN 1.4420 high-chromium austenitic stainless steel. The structural testing programme comprised ten pin-ended column tests as well as supplementary measurements of the initial global and local geometric imperfections of the column specimens. The structural testing programme was accompanied by a numerical modelling programme, including a validation study, where column finite element models were developed and validated against the experimental results, and a parametric study, where the validated column finite element models were employed to generate an additional numerical data bank over a broad spectrum of cross-section dimensions and member effective lengths. The obtained test and numerical data, were adopted to evaluate the applicability of the design provisions for normal stainless steel welded I-section columns, as set out in the current European code and American design guide, and cold-formed doubly symmetric section columns, as given in the existing Australian/New Zealand standard and American specification, to the new high-chromium stainless steel welded I-section columns. Overall, it was found that (i) all the four considered codes can be safely extended to cover the design of high-chromium stainless steel welded I-section columns, except for the American specification, which results in unsafe flexural buckling resistance predictions, and (ii) the most accurate and consistent design flexural buckling resistances were obtained by using the European code.

ABSTRACT: The Continuous Strength Method (CSM) provides accurate resistance predictions for both stocky and slender stainless steel cross-sections; in the case of the former, allowance is made for the beneficial effects of strain hardening, while for the latter, design is simplified by the avoidance of effective width calculations. Although the CSM strain limits can be used in conjunction with advanced analysis for the stability design of members, for hand calculations, the method is currently limited to the determination of cross-sectional resistance only, i.e. member buckling resistance is not covered. To address this limitation, extension of the CSM
to the design of stainless steel tubular section columns is presented herein. The proposed approach is based on the traditional Ayrton-Perry formulation, but features enhanced CSM cross-section resistances and a generalized imperfection parameter that is a function of cross-section slenderness. The value of the imperfection parameter increases as the slenderness of the cross-section reduces to compensate for the detrimental effect of plasticity on member stability that is not directly captured in the elastic/first yield Ayrton-Perry approach. The accuracy of the proposed approach is assessed against numerical results generated in the current study and existing experimental results collected from the literature. The presented comparisons show that the CSM provides consistently more accurate member buckling resistance predictions than the current EN 1993-1-4 design rules for all stainless steel grades. The reliability of the proposed approach is demonstrated through statistical analyses performed in accordance with EN 1990. Finally, the paper presents a framework through which the proposed approach can be developed for other cross-section types and materials.

ABSTRACT: Honeycombs based composites are applied in a wide spectrum of applications. In the present study, the performance of novel foam concrete filled auxetic aluminium honeycombs subjected to quasi-static and low velocity compression is experimentally and numerically investigated. The response mode, crushing resistance and energy absorption capacity of hollow and foam concrete filled auxetic honeycombs are experimentally studied under quasi-static and low velocity loading. Numerical models, validated with the test results, are employed in parametric study to further examine the performance. If properly designed, the interaction between the auxetic honeycomb and foam concrete reinforces each other, making the two components to work in synergy. It is found that the response modes of the composites change from compression failure with low peak stress and stable plateau stress to shear failure with high peak stress and severely fluctuated plateau stress with increasing foam concrete density. The response of foam concrete filled honeycombs gradually transforms from the quasi-static mode with global deformation to dynamic mode with localized crushing near loading end, and the effective Poisson's ratio of the composites decreases, both with increasing compression speed.

ABSTRACT: Recently, a new generation of cold-formed steel (CFS) channel sections with edge-stiffened circular holes have been developed by industry in New Zealand. No previous research, however, has considered the web crippling strength of CFS channel sections with edge-stiffened circular web holes under the interior-two-flange (ITF) loading conditions. In this paper, a combination of experimental investigation and non-linear finite element analysis (FEA) are used to investigate the effect of edge-stiffened holes under ITF loading conditions; for comparison, channel sections without holes and with unstiffened holes are also considered. In total, 30 web crippling test results are reported. A non-linear finite element (FE) model is described, and the results were compared against the test results, which showed a good agreement in terms of both the web crippling strength and failure modes. The results indicate that the stiffened web holes can significantly improve the web crippling strength of CFS channel sections. Using the validated FE model, a parametric study was conducted which include 1116 FE analyses, covering the effect of different hole sizes, edge-stiffener lengths and fillet radii, length of the bearing plates and position of the holes in the web. From the results of the parametric study, design recommendations in the form of web crippling strength reduction factors are proposed, that are conservative to both the experimental and FE results.

ABSTRACT: Lightweight auxetic reentrant honeycombs (ARH) with negative Poisson's ratio (NPR) are very promising for crashworthiness applications due to high specific-strength and energy-absorption (EA). To dig up the potential of ARH, a bio-inspired self-similar “concentric auxetic reentrant honeycomb (CARH)” is proposed to reinforce the EA. Finite element model is established and verified via available reference results for quasi-static-, low-, medium- and high-velocity compression. Two types of CARHs including CARH-I and CARH-II are designed to systematically explore the crashworthiness. The quasi-static and dynamic compression behaviors and EA characteristics are compared among different structures. There is a harvest that the bio-inspired CARHs show higher plateau stress and EA than the traditional ARH, while CARH-II > CARH-I. To clearly understand strengthening mechanisms, different global and uncellular shrinkage deformation modes (e.g., “x”, “X”, “T”, “V”, etc.) are revealed under different velocities. Summarily, the enhancement is due to coupling deformation and energy-dissipation of more plastic-hinges. The horizontal strain of each layer is studied to reveal the NPR effect, which shows a significant velocity effect on the horizontal strain. From parametric studies, typical parameters (e.g. wall-thickness, distance and number of concentric walls) have considerable effects on crashworthiness of CARH. The present bio-inspired design and findings offer a reference for the development of honeycomb with special functions.

ABSTRACT: This paper presents an investigation on the performance degradation of circular thin-walled concrete-filled steel tubular stub columns in the high-latitude offshore region. 24 specimens were loaded axially after freeze-thaw cycles and salt spray corrosion. The results show that with the increase of corrosion rate and concrete grade, the strength degradation of the specimens after the peak point becomes severe. The increase of corrosion rate approximately linearly reduces the ultimate strength of the specimens after freeze-thaw cycles, regardless of concrete grade. The ductility index and the composite elastic modulus of the circular thin-walled CFST stubs are decreased by corrosion after freeze-thaw cycles. Two design methods are proposed based on the discussions of the test results. The simplified design method for predicting the ultimate strength is proposed and validated based on the test results. The design method in Eurocode 4 for the ultimate strength is improved, in terms of material property degradation. A full-range prediction of the strength degradation of circular thin-walled CFST stubs under freeze-thaw cycles and corrosion is conducted. It is concluded that the high strength of core concrete is beneficial for the duration ability of thin-walled CFST stub columns.

ABSTRACT: The shear strength, shear distortion, failure mode, and energy absorption performance of irregular circular and box-shaped tubular column panel zones (PZs) were investigated using experimental and analytical methods on the seven steel frame structures. The main parameters include the beam height ratio of left and right beams, the column cross-section, and the configuration of external diaphragm. The key variable, beam height ratio, can affect the PZ shear strength and energy absorption, but has little influence on the initial stiffness of the PZ; the PZ, PZ1, and PZ2, absorb energy together in the initial loading stages, as the load increases, most of the energy begins to be absorbed only by PZ1 which has the same height as the smaller beam, therefore, the design considering only PZ1 is incomplete; excessive PZ shear deformation can cause cracking of the weld root which adversely affects the structure; the configuration of external diaphragm should avoid stress concentration which can cause cracking of the base metal. The chosen analysis methods are capable of simulating the shear strength and failure modes of the PZ obtained in experimental results with acceptable accuracy.

ABSTRACT: The current investigation deals with the nonlinear oscillation response of conical microshells made of a composite material with functional graded (FG) in-plane heterogeneity is studied in the presence of
the size dependency. To accomplish this purpose, various types of homogenization schemes including Voigt model, Reuss model, Mori-Tanaka model, and Hashin-Shtrikman bounds model are employed. The size-dependent characteristics are taken into consideration on the basis of the modified couple stress theory of elasticity within the framework of the higher-order shear deformation shell theory. The couple stress-based differential equations of motion are constructed via the Hamilton's principle. An efficient numerical solution methodology adopting generalized differential quadrature (GDQ) method together with the pseudo-arc technique is put to use to obtain the modified couple stress-based nonlinear frequency of homogenized FG composite conical microshells. It is demonstrated that by increasing the value of the maximum shell deflection, the couple stress type of size effect plays more important role in the nonlinear vibration response of FG composite conical microshells. Additionally, it is indicated by changing the boundary conditions from simply supported one to clamped one, the influence of couple stress size dependency decreases.

ABSTRACT: It has been shown that fire disaster normally occurs following an earthquake disaster, which might cause even more serious losses than the earthquake itself. This study investigates the post-earthquake fire performance of concrete-filled steel tube (CFST) columns. The experimental programme contains two parts - quasi-static tests and fire tests. During the quasi-static tests, the square CFST columns were loaded under constant compressive force and cyclic horizontal force, until reaching different degrees of seismic damage. Afterwards, the pre-damaged columns were loaded under a constant axial compression ratio (i.e. ratio of the applied compressive load to its bearing capacity) of 0.3 at elevated temperatures. The fire resistance time and failure modes of these pre-damaged CFST columns were reported. Finite element (FE) models were developed and validated against the test results; a total of 48 numerical results were generated in the parametric study using the validated model. In the parametric study, the influence of key parameters including the thickness of steel tube, the yield strength of steel tube, the axial compression ratio and pre-damage degrees on the fire resistance of square CFST columns were analysed. The experimental and numerical results are used to propose design rules for the fire performance of square CFST columns with different degrees of seismic damage.

ABSTRACT: Modular construction has become popular for its advantages in construction efficiency and reduced manpower on site. Steel modules are typically connected using bolted connections which often suffer from inadequate allowable tolerances to accommodate imperfections due to vertical alignment of modules. To solve these problems, a shear-keyed grouted sleeve connection (SK-GSC) is proposed to connect the square hollow section (SHS) columns between the upper and lower modules. This paper investigates the axial performance of SHS SK-GSCs, specifically on their resistance and load transferring mechanism. To study the effect of shear key spacing, grout strength, and grout thickness, fifteen specimens were tested, and numerical models were calibrated against the test results to gain insight into the failure mechanism. It was found that the load-bearing resistance of SHS SK-GSCs was contributed by the frictional bond at the steel-grout interface and the diagonal compression struts developed in the grout. The proposed connections have sufficient axial resistance, stiffness and ductility to integrate the module columns vertically as compared to existing bolted connections. They were robust enough to withstand potential tension force due to accidental action in the design of modular buildings.

ABSTRACT: Columns with initial crookedness and twist are analyzed. A discrete elastic restraint resists bending and twisting as the compressive load is increased. The thin-walled columns are linearly elastic, and deformations are small. Numerical results are presented for two examples of pinned columns with half-sine
initial imperfection shapes. The first is a singly symmetric Cee section with torsional bracing. Flexural-torsional coupling occurs between the twist and bending in the strong direction. The second is a doubly symmetric I section with lateral bracing on one flange. Flexural-torsional deformation in this case involves twist and bending in the weak direction. The effects of axial load, bracing location and stiffness, and relative orientations of the imperfections are investigated. Also, the stiffness required to restrict the twist to be a certain proportion of the initial twist is determined, which is useful for designing bracing.

ABSTRACT: In the present paper, an improved procedural method for the generation of curved, arbitrarily conformed self-stiffened panels using skeleton-based integral soft objects is presented. The proposed approach extends the application of integral soft objects to curved mesh surfaces by operating an inverse anamorphic mapping of special-purpose displacement fields applied orthogonally to the patched surface representing the curved structural domain. An efficient parallel procedure, able to evaluate the vector field of normals at mesh nodes of the host domain, is preliminary illustrated. Several multi-map techniques are subsequently exploited to generate arbitrary protrusions on different curved mesh surfaces, either open or closed.

ABSTRACT: The utilization of membrane structures in space engineering has attracted considerable attention in recent decades due to ultra-light weight characteristics. The measurement and calibration of dynamic performance on ground is challenging due to air effects and equipment limitation. In this paper, a novel vacuum-level vibration-testing device is developed to realize an environment of adjustable air pressure. An improved membrane tension system is utilized to guarantee simply-supported boundary conditions and a uniform stress field, which is more consistent with theoretical and simulation requests. The modal identification method is modified based on only four measuring points because of limited space of the vacuum tank, which is a combination of FFT (Fast Fourier Transform) and SSI (Stochastic Subspace Identification) methods. The effects of non-uniform stress field and air pressure on membrane modal are investigated based on the proposed testing device and method. The effect of the non-uniform stress field on membrane frequency is analyzed by the theoretical, numerical and experimental methods, and the results show that the non-uniform stress field resulting from uneven tensions has little effect on the frequency of biaxial tensioned membranes. Meanwhile, an empirical formula is proposed to predict the first three structural frequency of a specific biaxial tensioned membrane under different air pressures.

ABSTRACT: The nonlinear parametric resonance of a cantilever under axial base excitation is examined while capturing extremely large oscillation amplitudes for the first time. A geometrically exact model is developed for the cantilever based on the Euler-Bernoulli beam theory and inextensibility condition. In order to be able to capture extremely large oscillation amplitudes accurately, the equation of motion is derived for centreline rotation while keeping trigonometric terms intact. The developed model is verified for the static case through comparison to a three-dimensional nonlinear finite element model. The internal energy dissipation model of Kelvin-Voigt is used to model the system damping in large amplitudes more accurately. The Galerkin modal decomposition scheme is utilised for discretisation procedure while keeping the trigonometric terms intact. It is shown that in parametric resonance region, the oscillation amplitudes grow extremely large even for smallest possible amplitudes of the base excitation, which highlights the significant importance of employing a geometrically exact model to examine the parametric resonance response of a cantilever.

ABSTRACT: This study presents the experimental and numerical investigation of the response of hemispherical sandwich shell structure having hexagonal honeycomb core against ogive nosed projectile impact. Aluminum AA-1100 was considered for the front and rear face sheet of 200 and 160 mm diameter whereas AA-3003H19 was used for the honeycomb core of 3.2 mm cell size, 0.05 mm cell wall thickness and 20 mm core thickness. The cylindrical ogive nosed projectile having diameter 19 mm, mass 52.5 g and length 50.8 mm was hit at the crown of the hemispherical sandwich shell structure. The experiments were carried out through a pneumatic gun whereas for numerical simulations, 3D finite element code Abaqus explicit solver was used. The ballistic resistance, failure mechanism and the energy absorption of the sandwich shell structure was investigated thoroughly through experimentation and numerical simulations and found close to each other. Moreover, the parametric study was performed through numerical simulations to study the influence of face sheet thickness (0.7, 1, 1.5 and 2 mm), cell wall thickness (0.03, 0.05, 0.07 and 0.09 mm) and cell size (3.2, 5.0, 7.0 and 9.0 mm) of the honeycomb core on the ballistic response and energy absorption. Against ogive nosed projectile, face sheets failed in radial stretching with petal formation and the core failed in crushing. Also, the face sheet thickness had a dominant effect on the ballistic limit and the energy absorption of the hemispherical sandwich shell structure. Moreover by increasing core stiffness (by using thick cell wall and small cell size) enhance energy absorption capacity of the sandwich structure.

ABSTRACT: In the present study crashworthiness performance of monolithic and co-axial multi-wall (double, triple, and four layered) frusta tube structures was investigated under the quasi-static axial loading. The developed layered frusta tubular structures having a total equivalent thickness of 2.3 mm were made of aluminium alloy AA-1080 sheet. A series of layered configurations were simulated and analysed using non-linear finite element analysis code LS-DYNA, keeping volume approximately the same as the monolithic frusta tube. For the effectiveness of the simulated results, double-tubular structure was examined through experimental results. A parametric study was performed by keeping taper angle constant as 5.71° with the variation in height (91.6 and 82 mm for double layered, 91.6, 86 and 78 mm for triple layered and 91.6, 87, 82 and 77 mm for four layered), thickness (2.3–0.4 mm) and diameter (smaller end diameter in the range of 42.8 mm–48.4 mm while larger end diameter varied from 61 mm to 64 mm) to analyse the crushing performance of layered structures. The crashworthiness performance indicator like peak force (PF), mean force (MF), energy absorbing capacity (EAC), specific energy absorption (SEA) and crush load efficiency (CLE) which is defined as the ratio of MF to the PF, were studied for the various layered frusta tubular structures. Moreover, optimization technique GRA (Grey Relational Analysis) was employed to obtain a better combination of multi-wall layered structures. With the increase in the layer, the initial peak force was reduced compared to the monolithic frusta. The optimization technique suggested the triple-layer configuration showed better crashworthiness performance.

ABSTRACT: Stiffened plate widely exists in ships, steel girders and wing of airplanes for its good bending resistance and lighter weight. The main purpose of this work is to investigate the dynamic response of stiffened plate subjected to confined blast loading through both experimental and numerical approaches. Firstly, several field blast experiments of box-shaped specimens with different dimensions and different explosive weight were conducted. The damage features of both inner-stiffened and outer-stiffened plate were obtained and investigated. Then, numerical models were built and validated by the experimental results, and the dynamic response processes were analyzed. Both the experimental and numerical results show that outward deformations
produced in both inner-stiffened and outer-stiffened plate, while the ultimate deflection of outer-stiffened plate is smaller than that of inner-stiffened. In the meantime, overall bending deformations are observed in the outer stiffeners, while in-plane bulking of the flanges and instability failure of the web are observed in the inner stiffeners. In addition, the different dynamic response of stiffened plate under confined and unconfined blast loading were analyzed and compared using the validated numerical method, and the tendency of the dimensionless deflection of inner and outer stiffened plates subjected to confined blast were discussed.

ABSTRACT: The crumpling of aluminium alloy AA6060 T4 thin-walled tubes when subjected to axial and oblique impact is often experienced in collisions. Tubes with holes (so-called windows) and multi-cell tubes are efficient in terms of the structure's energy absorption. This paper proposes a combination of rectangular windows and multi-cell square tubes to improve the structure's crashworthiness. The advantages of the introduction of windows into the structure can diminish the initial peak collapsing load. This can also improve the crashworthiness performance and the mechanism of a folding formation. However, this introduction causes cracks in the tube and thus reduces the plastic zone area of the fold. The decrease in the plastic zone area and the cracks reduce the tube's energy absorption capacity. The specific energy absorption (SEA) and mean collapsing load \( P_{c,\text{ave}} \) of WMCT-I and WMCT-III under axial impact is higher by about 20% and 16% compared to those of MCT-I and MCT-III, respectively. Relating to MCT-II having a wall-to-corner (WTC) one, the tube with holes does not improve in either case of axial and oblique impact. Extensive theoretical solutions are proposed to predict the mean collapsing loads of the windowed multi-cell tubes. The results of the theoretical predictions are compared to those of the numerical simulation. The Multi-Criteria Decision Making (MCDM) method is applied to select the better structure for the energy absorber application.

ABSTRACT: In this study, the experiments of 800 MPa high strength steel (HSS) welded I-section columns under axial compression are performed to investigate their local buckling behavior. The effects of width-to-thickness ratio and slenderness on the local buckling load are considered. Four different buckling modes of columns (i.e., web buckling, flange buckling, web and flange buckling, and global buckling) are designed. The local buckling load obtained from load-displacement curves and load-strain curves are investigated. New embedding coefficients of the web and flange in 800 MPa HSS welded I-sections are recommended. Design provisions in current specifications for predicting the ultimate bearing capacity of 800 MPa HSS welded I-section columns under axial compression are evaluated, and it is concluded that GB50017-2017, AISC360-16, and EN 1993-1-5 is a little overestimated for estimating the ultimate bearing capacity of 800 MPa HSS welded I-section columns under axial compression. A three-dimension finite element model is developed for predicting the ultimate bearing capacity of 800 MPa HSS welded I-section columns under axial compression, which is validated by test data. The effect of residual stress on the ultimate bearing capacity of 800 MPa high strength steel welded I-section columns is not obvious. A more accurate model for estimating the ultimate bearing capacity of 800 MPa HSS welded I-section columns under axial compression is recommended.

ABSTRACT: Free axisymmetric vibrations of composite annular sandwich plates with thick isotropic core and orthotropic facings have been studied using Reddy's higher-order shear deformation theory. Core is assumed to be of uniform thickness while the face sheets are treated as membranes. Equations of motion and natural boundary conditions are developed using Hamilton's principle. Chebyshev collocation technique has been applied to get the frequency equations for clamped-clamped, clamped-simply supported and clamped-free edge conditions. Obtained equations are solved numerically for the lowest three roots and reported as the frequency
parameters for the first three modes of vibration. Results obtained from the proposed approach are validated by comparing them numerically and graphically with their counterparts available in the literature. Detailed numerical results are given to analyze the effects of core thickness, thickness of faces and radii ratios on the frequency parameter. It is also shown that the published analysis based on first-order theory is not suitable for estimation of natural frequency of annular sandwich plate with thick core. Three dimensional mode shapes have been plotted for a specified plate for all the three boundary conditions.

ABSTRACT: This paper presents an investigation into the energy absorption behaviour of splitting multiple circular tubes by theoretical, experimental and numerical methods. A theoretical solution for the steady-state crushing force of splitting multiple circular tubes is derived by applying the deformation theory. To explore the energy absorption of splitting multiple circular tubes and to validate the finite element model and a theoretical solution for the crushing force, an impact experiment is performed using a test trolley to examine the splitting process and force responses of multiple circular tubes. The finite element models of splitting multiple circular tubes are then established to investigate the energy absorption behaviour of the structure. The numerical simulation results agree well with those of the impact experiment. The energy absorption of splitting multiple circular tubes with different geometrical configurations, including the wall thickness of the tubes, number of tubes, radius of the tubes and conical angle of the dies, is analysed using a validated finite element model. The results show that the geometrical configurations of the tubes and conical angle of the dies have a distinct effect on the energy absorption. An analysis is also conducted to investigate the energy absorption by the evolution of the theoretical models. It is confirmed that the theoretical solutions provide a reliable prediction of the steady-state crushing force of splitting multiple circular tubes. The effect of the velocity is investigated, and the result shows that the steady-state force increased as the impact velocity increased.

ABSTRACT: The response of non-slender flax fibre reinforced polymer (FFRP)-skinned foam filled tubes under axial compression was investigated using 39 specimens. Different cross-ply fibre arrangements and foam densities (33–65 kg/m) were tested; the responses were compared to hollow FFRP tubes and Glass-FRP (GFRP) skinned tubes. Although axial behaviour was not significantly affected by changing foam density, hollow tubes were weaker than foam filled sections. This suggests that low density foam is effective at preventing premature failure. FFRP-skinned tubes with a skin thickness of 6.4 mm behaved similarly to GFRP-skinned tubes with a skin thickness of 3.4 mm in terms of strength and stiffness but were considerably better at absorbing energy. Specific strength and stiffness were highest with the lightest foam. The best performing FFRP-skinned tubes had specific strengths about 75% that of GFRP-skinned tubes with similar dimensions and equivalent foam cores.

ABSTRACT: The important claim that the presence of the structural damping considerably lessens or even eliminates the effectiveness of the embedded shape memory elements in the dissipation of the vibration/impact energies of the structures, is stated and proven here for the first time. The finite-element-based governing equations of thick composite sandwich plates with homogeneous/FG soft viscoelastic cores and embedded SMA wires are derived based on a new hyperbolic SMA-zigzag sandwich plate theory that considers the transverse flexibility. The tension-compression asymmetry of the SMA behavior and Zener-viscoelasticity-based zigzag nonlinear corrections are implemented to guarantee the transverse stress continuity at the interfaces between layers and updating the relation between the describing parameters of the displacement field,
and the stiffness and even mass matrices of the elements within each time step. For the first time, the phase-based rather than the mixture-based stresses are considered in tracing the phase transformations. The resulting time-dependent nonlinear integro-differential equations are solved by a special algorithm. Results confirm, for the first time, that the stress-strain hysteresis loops of the SMAs may shrink or even disappear in presence of the structural damping; so that, the belief that the phase-transformation-based damping and the structural damping directly add to each other, is quite wrong.

ABSTRACT: In practice, the foundations of arch bridges or other arch structures may have non-uniform settlements leading to uneven movements or rotations of the supports of the arch. The uneven movements and rotations of the supports influence the deformations and internal forces produced by the external load as well as the in-plane non-linear instability behaviour of arches significantly. Little research is reported about effects of support movements and rotations on the nonlinear in-plane instability of shallow arches in the opening literature. This paper focuses on effects of uneven movements and rotations of the supports on the in-plane nonlinear instability of fixed shallow arches. New analytical solutions for the limit point instability load of the fixed shallow arches under a uniformly localized radial load incorporating the influences of uneven movements and rotations of the supports are derived. Comparisons against the finite element results show the analytical solutions are adequately accurate. It is found that the uneven support movements and rotations have significant effects on the nonlinear in-plane instability behaviour of fixed shallow arches. It is also found that the in-plane nonlinear instability load of a fixed shallow arch decreases with an increase of the magnitudes of uneven movements and rotations of the support.

ABSTRACT: Thin-walled shell structures such as those used for space launch vehicles are highly sensitive to various kinds of imperfections. This imperfection sensitivity makes it challenging to predict the load carrying capacity of these structures. A correlation between the manufacturing process and the load carrying capacity, called manufacturing signature, would facilitate the design of these structures. Therefore, in this paper, a step towards a manufacturing signature of flow formed unstiffened isotropic shell structures is made. For this purpose, the investigated shell structures and their manufacturing process are introduced in detail in this work. Afterwards, the geometric and thickness imperfections of these shell structures are measured using an in-house developed measurement system. The measurement results are evaluated in detail and the buckling loads of the measured shell structures are calculated numerically. The results show that all six shell structures have similar knock down factors, which indicates a correlation between the manufacturing process and the load carrying capacity. Subsequently, experimental buckling tests are carried out for three shell structures. The discrepancies between the numerically calculated and the experimentally measured buckling loads are tracked back to load imperfections. Finally, the impact of load imperfections is studied briefly.

ABSTRACT: A type of self-lock multi-cell tubes assembled by open section components is recently proposed to serve as energy absorbing devices. Due to the open feature of the section, the self-lock tubes with large width may develop global buckling mode under axial crushing and show much worse energy absorption performances. To overcome this drawback, expanded polystyrene (EPS) foam fillers are firstly employed to improve the stability of the structural deformation and to increase the energy absorption efficiency. Experiment results show that a 4% increase in mass by EPS foam leads to about 20% increase in energy absorption of the self-lock tube. Numerical analyses are also carried out to simulate the tests and analyze the structures with other enhancement methods including Al foam filling and tube enveloping. They may be employed separately or simultaneously. The combination method of Al foam filling and tube enveloping gets the highest energy
absorption capacity and efficiency. Theoretical analysis is performed to predict the mean crushing force of self-lock tubes enhanced by Al foam filling and tube enveloping, and the theoretical results compare well with numerical results. Finally, crashworthiness optimization problems are proposed and solved to explore the optimal enhancement configurations of the self-lock multi-cell tubes.

ABSTRACT: The study aims to understand the effect of stacking sequence on the impact response and residual flexure characteristics of braided composite tube by combination of low-velocity impact, fracture observation and acoustic emission monitoring. Two stacking sequence configurations of braided tube in terms of [60°/40°] and [40°/60°] were designed and their low-velocity impact response and damage behavior were examined. Uniform structures namely [40°/40°] and [60°/60°] were also employed as reference specimens. The quasi-static bending performances of intact and impacted tubes were further compared to evaluate the influence of impact damage on residual performance. The results show that failure mode of impacted tubes strongly depends on braided structure of outer ply, of which large braiding angle(60°) leads to the formation of bottom delamination and degradation of structural integrity. The comparative experiments indicate that [60°/40°] tube improves flexure after impact performance with respect to specific energy absorption by 45.98% over [40°/60°] counterpart because of absence of bottom delamination. Thus, structure design of braided composite consisting of intra-ply structure and stacking sequence would be an economically feasible method to improve the transverse mechanical performance.

ABSTRACT: In this study, the strengthening effects of carbon fiber-reinforced polymer (CFRP) on the shear strength of thin-walled steel plates (TSPs) were investigated using experiments and finite element analysis (FEA). Two types of CFRP with different fiber orientations—0°/90°, and ±45°—were used for strengthening. The experimental and FEA results indicate that CFRP could effectively increase the shear strength of TSPs under shear loading. The theoretical equations according to the lamination theory of composite materials are proposed to calculate the shear strength of CFRP-strengthened TSPs under shear load with high accuracy compared with experimental and FEA results.

ABSTRACT: This paper presents a numerical investigation on the design resistance of extruded aluminum beams subjected to concentrated loads. The study is conducted through nonlinear finite element analysis considering large displacements, initial imperfection, and taking into account the strain hardening characteristics of common aluminum alloys. The numerical model is validated against experimental works taken from the literature. Thereafter, an extensive parametric study is carried out covering a wide range of beam geometries and slenderness ratios. Resistances computed numerically are compared with those calculated using the current design provisions in the EC9 for aluminum beams subject to concentrated loads, indicating that the EC9 provisions underestimate the resistances. Then, a new resistance function is calibrated performing a statistical evaluation of experimental and numerical results. The reliability of the recalibrated resistance function is assessed according to EN 1990, the results show improvements in the predicted resistances. Finally, the use of more accurate structural design provisions enhances the possibility of higher economic benefits, and by using less material, the carbon footprint originated from aluminum production can be reduced.

ABSTRACT: Design of multi-cell sectional configuration has been considered an effective way to enhance the crashworthiness performance of metallic thin-walled structure. Nevertheless, it remains under-studied whether this approach can achieve similar effect for fiber reinforced composite structures. Therefore, this paper aims to study the crushing responses and energy absorption behaviors of multi-cell squared carbon fiber reinforced plastic (CFRP) tubes fabricated by using hot compression molding process. The effects of CFRP cell number, wall thickness and trigger mechanism on crashworthiness characteristics were investigated. The experimental results showed that under the same weight, the energy absorption of double-cell tube was lower than that of single-cell tube. This was due to the fact that there was insufficient deformation in the T-shaped region of double-cell CFRP tube. The inner fronds generated in the middle ribs caused part of tubal wall near T-shaped region to bend completely outwards rather than to crush progressively under axial compression, thus losing certain capacity of energy absorption. In addition, a double-shell finite element model was constructed to gain further insights into the crushing behavior of the double-cell CFRP tube. The numerical model effectively replicated the collapse mode; and good agreement was obtained between the experimental and numerical load-displacement curves. The study exhibits considerable potential of developing crashworthy multi-cell CFRP structures.

ABSTRACT: The effect of the number of carbon-fiber-reinforced plastic (CRFP) layers on the axial crushing capacity of aluminum–CFRP square hybrid tubes was investigated both experimentally and numerically. Increasing the number of CRFP layers led to more collapsed lobes and decreased collapsed lobe widths, resulting in an improvement of the energy absorption capacity. The simulation results revealed a distinct tube wall collapse mode in the 4-layer hybrid tubes. The higher bending stiffness of the composite layers in the 4-layer hybrid tube led to debonding of the interface between the aluminum and composite layers. After interface failure, the composite layers did not collapse following the aluminum tube wall and instead rebounded in the approximate longitudinal direction, which directly suffering the longitudinal crushing loading. This behavior led to the shortened plastic collapse width and improvement of the single-layer CFRP energy dissipation due to CFRP delamination.

ABSTRACT: This work aims to improve upon the aluminium impact attenuator currently used by the University of Lisbon Formula Student team through a composite solution. The influence of geometrical variations, particularly the use of curved walls, and the number of objectives considered for the optimization are studied. To perform the optimizations, Abaqus is coupled with the Direct Multisearch (DMS) algorithm, the overall performance of the solutions is evaluated and the influence of the introduction of curved walls on the energy absorption capabilities discussed. Off-axis impacts are studied and the effect of curved walls in that situation analysed. An overview of the best configurations achieved is provided and one final configuration is selected.

ABSTRACT: The present work is focused on the investigation of tetra-anti-chiral structures by means of experimental, numerical, and analytical methods. Specimens with different lengths of the ligaments were manufactured by laser-cutting and were tested under a compressive load to investigate the value and evolution of Poisson's ratio. Based on the experimental investigation of the material used to manufacture the samples, finite element models were developed and solved using Ls-Dyna. Subsequently, based on the strain energy approach, an analytical solution for the estimate of the Poisson's ratio was derived. The solution is capable of estimating the value for structures with various configurations, including lengths and thickness of the ligaments. A simple beam finite element model was developed and implemented for solving in MATLAB, to extend the
capabilities for evaluation and design of structures with specific parameters. An overall comparison of results is presented, showing a good agreement between datasets. The present work might set the background for future activities, allowing for a selection of individual investigation methods.

ABSTRACT: In this paper, flexural stiffness reduction factor formulations, applicable to stainless steel members with compact cold-formed square and rectangular hollow section (SHS and RHS), are extended to account for local buckling effects and initial localized imperfection (ω). Local buckling effects and the influence of ω are accounted for by means of reducing the gross section resistance using a strength reduction factor ρ, determined by the Direct Analysis Method, depending on cross-section slenderness, is adopted. For in-plane stainless steel elements with non-compact and slender sections, results determined by the extended flexural stiffness reduction factor coupled with Geometrically Nonlinear Analysis (GNA) are verified against those determined by Geometrically and Materially Nonlinear Analysis with Imperfections (GMNIA). It is found that GNA with the extended flexural stiffness reduction factor (using beam element) generally achieves the accuracy of GMNIA (using shell element). Probabilistic studies based on 3D models with random ω are carried out to evaluate the effect of uncertainty in ω on the accuracy of GNA with the extended beam-column flexural stiffness reduction factor.

ABSTRACT: A typical fiber-reinforced polymer (FRP)-concrete-steel double-skin tubular column (DSTC) consists of an FRP outer tube, a hollow steel inner tube and an annular concrete in-fill in between. The existing studies on DSTCs in the past decade have generally confirmed the good structural performance of such column form, while it is worth noting that the possible in-ward buckling of the steel tubes in DSTCs is still a problem to be addressed, especially when DSTCs are subjected to large axial deformation. Against this background, a variation form of DSTCs called R-DSTCs has been recently developed by the authors. An R-DSTC is a DSTC in which the steel inner tube is reinforced by vertical stiffeners on the outer surface and the FRP outer tube can be circular, square or rectangular. The present paper presents the first ever experimental study on the compressive behavior of circular R-DSTCs which is the most common form of DSTCs. For the circular R-DSTC specimens tested in the present study, the outer tubes are made of a type of large-rupture-strain FRP. The vertical stiffeners on the steel inner tube are expected to delay or restrain the inward buckling of the steel tube, and the large-rupture-strain FRP outer tube makes possible a relatively large axial deformation of the specimen. In total, two DSTC specimens, twelve R-DSTC specimens and three bare steel tubes with/without stiffeners were tested, with the studied parameters covering the quantity, the dimensions and the shape of the stiffeners and the thickness of the FRP outer tube. The test results showed that R-DSTC specimens had a much better performance than the corresponding DSTC specimens in terms of both axial loading capacity and ductility, due to the existence of vertical stiffeners on the steel inner tube of R-DSTCs. The effects of the vertical stiffener-related parameters on the compressive behavior of R-DSTC specimens were also carefully examined and discussed in details.

ABSTRACT: In this study, two dimensional double-U auxetic honeycombs (2D DUHs) composed of curved shell members have been proposed based on traditional double-V (concave quadrilateral or re-entrant double-arrowhead) auxetic honeycombs (2D DVHs). Theoretical analysis, numerical simulation and compression experiments are adopted to characterize the mechanical properties including equivalent Young’s modulus,
equivalent Poisson's ratio, and quasi-static collapse process of 2D DVHs and DUHs. Specimens of the 2D DUHs and DVHs made of Aluminum alloy (A6061) are fabricated through wire cut electrical discharge machining. Both numerical and experimental results illustrate that concave DUHs exhibit tunable negative Poisson's ratio and equivalent stiffness level compared to DVHs. Furthermore, DUHs have smooth geometry configurations that can reduce stress concentration at elastic region and exhibit stronger auxetic behavior during large deformation. Those mechanical properties of 2D DUHs satisfy the requirements for practical engineering applications such as energy absorption. The dynamic crushing responses of 2D DVHs and DUHs are also investigated, and it is found that the crushing collapse modes and plateau stress improvement of 2D DUHs are related to the crushing velocity. Finally, the local impact responses of 2D DVHs and DUHs are studied numerically, the influences of impact velocity and indenter size are considered. This study provides useful instructions for the design, fabrication and analysis of auxetic structures, which has a broad prospect in some advanced technical applications.

ABSTRACT: Organisms in nature can inspire human research and design. Bamboo is generally acknowledged to be the structure with the best specific energy absorption and specific stiffness in nature. Compared to trees, it is difficult to break bamboo at its root and cause it to fall under dynamic loads, which can provide a useful reference for researchers. In this paper, a tube–diaphragm coupling beam inspired by bamboo was designed. The dynamic model of the bending vibrations of was established for the first time, and the influences of the structural parameters, such as the number of diaphragms, the tube thickness, and the impact pulse width on the impact characteristics of the tube–diaphragm coupling beams under transverse impact forces were analyzed. An optimal design of the tube–diaphragm coupling beams was obtained by particle swarm optimization. Specimens of bionic, solid, and hollow beams were prepared by the SLA (stereo lithography apparatus) 3D printing technology, and impact tests were carried out. The results of impact tests showed that the base vibrations of the solid and hollow beams were greater than those of the tube–diaphragm coupling beam for different impact pulse widths. The results indicated that bamboo can change its natural frequencies by adjusting the number of diaphragms and the tube thickness to adapt to changes of the environment. This adjustment can make the tube–diaphragm coupling beam absorb more energy through deformation, and thus, the dynamic force of the tube–diaphragm coupling beam at its root was smaller than those of solid and hollow beams. The results reveal the mechanism that allows bamboo to be difficult to beak at the root and fall, which can provide a useful reference for the design of beams and rotors.

ABSTRACT: The paper proposes a carbon fiber tube reinforced polyurethane foam material (CPM). Mechanical behavior of the CPM is investigated by quasi static crushing experiment. The results show that the carbon fiber tube reinforced design can obviously improve the energy absorption and load carrying capacity of the polyurethane (PU) foam. Parameter studies show that the density of the PU foam, the number and the diameter of the thin carbon fiber tube have significant effect on mechanical performance of the CPM. Moreover, the CPM filled thin walled columns (aluminum column or carbon fiber column) are further developed and their crushing behaviors are investigated under axial crushing conditions. The results show that the CPM filled design can effectively improve the crashworthiness of the aluminum column or the carbon fiber column. The interaction behavior between the CPM and the thin-walled column presents a significant contribution to energy absorption of the CPM filled columns. Moreover, the CPM filled carbon fiber column has greater potential to improve the crashworthiness than the CPM filled aluminum column. The research findings of this paper provide a new method for designing the lightweight protective structure.

ABSTRACT: This paper presents the application of higher-order shear deformation theory and nonlocal elasticity theory to electro-mechanical vibration analysis of a doubly curved piezoelectric nano shell resting on Pasternak's foundation. The piezoelectric doubly curved nanoshell is subjected to initial electro-mechanical loads. Effect of initial electro-mechanical loads is contributed in external works. Size effects are captured by nonlocal elasticity theory and Hamilton's principle is employed to derive the equation of motion in terms of three displacements of the middle surface, two rotational components and one electric potential. The main novelty of this paper is investigating concurrent effect of initial electro-mechanical loads, higher-order shear deformation theory and size dependent theory on the free vibration responses of doubly curved piezoelectric nano shell with various boundary conditions. The electro-mechanical vibration response of the doubly curved piezoelectric nano shell is investigated using an analytical method in terms of various parameters such as two opening angles, small scale parameter, spring and shear parameters of foundation and initial electric potential. It is concluded that increasing the applied electric potential increases the natural frequencies.

ABSTRACT: Due to high sensitivity to various imperfections, buckling loads of thin-walled cylindrical shells subjected to axial load vary dramatically. In order to predict lower-bound buckling loads for axially loaded cylindrical shells rationally, a probabilistic analysis approach named Probabilistic Random Perturbation Load Approach (PRPLA) is developed in this study. Firstly, a Back-Propagation Neural Network (BPNN) based method is established to describe measured imperfection patterns. Next, Random Single Perturbation Load Approach (RSPLA) is loaded upon BPNN-based depicted traditional imperfection patterns to construct a stochastic dimple imperfection. The aforementioned scattering traditional imperfections, as well as a variety of scattering non-traditional imperfections, are then sampled using Monte-Carlo simulation to generate cylindrical shell models differentiating from a nominal one. The probabilistic distribution of lower-bound buckling loads is obtained by finite element analysis. A nominal shell's realistic lower-bound buckling load is determined by choosing a specified reliability level lastly. The results show that describing measured imperfection patterns via BPNN is very close to real ones, and PRPLA presented is an improved method to find lower-bound buckling loads efficiently compared with NASA SP-8007 and many commonly used numerical approaches.

ABSTRACT: Metallic grid stiffened cylinders are often used as tank and interstage structures in launch-vehicle systems. When subjected to axial compression, these thin-walled shells are prone to buckling. The corresponding critical buckling load heavily depends on deviations from the ideal shell shape. In general, these deviations are defined as geometric imperfections and they can significantly reduce the critical load. Considering the influence of geometric imperfections into the design process of thin-walled shells poses major challenges for structural design. This article presents an overview regarding the modelling, analysis and design of metallic grid stiffened launch-vehicle cylinders. In comparison to commonly studied unstiffened cylinders, complex shells applied in aerospace engineering can have a completely different structural response to axial compression than their unstiffened counterparts. Advanced shell buckling design concepts like perturbation approaches and energy barrier criteria are applied and validated with experimental data. Finite element models are presented and described in detail. Important aspects like skin and weld buckling as well as the influence of cutouts are analyzed and discussed.

ABSTRACT: As a lightweight and efficient energy-absorbing structure, thin-walled filled structure is widely used in various fields. This paper proposed four types of bio-inspired foam-filled thin-walled structures based
on two typical straw structures (Cornstalk and Reed): bionic foam core with a central hole, 4 square holes, 4 taper holes and 2 nodes, respectively. The energy absorption capacity and deformation mode of bionic structures were studied by dynamic drop hammer and quasi-static compression. The results showed that 9 of 12 bionic samples had higher energy absorption capacity than the corresponding fully-filled samples. Different bionic features have different effects on the deformation of thin-walled tube, and the bionic features with the best overall performance are the 4 Square Holes and 4 Taper Holes design. It is noted that the bionic method can improve energy absorption capacity and affect the deformation mode of the thin-walled tubes under certain conditions.
